ABSTRACT

The present thesis focused on the development of modified titania nano photocatalysts to synergise enhanced visible light photocatalysis that niched for the destruction of lethal aquatic pollutants. In preliminary phase template TiO_2 was successfully synthesised through a facile non-hydrolitic sol-gel technique. The materials chemistry revealed the pristine anatase phase and crystallinity of TiO_2 . It also demonstrated the influence of crystallinity over photocatalysis efficiency. This was well reflected in photocatalysis evaluation studies under solar irradiation where good crystallinity shown a better photodegradation performance over the non-crystalline. The inherent photocatalytic characteristics of the synthesised TiO_2 was modified and enhanced by incorporating the noble characteristic derived from palladium (Pd) and silver (Ag). This was achieved through a smart, ease and sustainable method. The adopted novel method explicitly revealed the capability of sunlight for anchoring the noble metal onto TiO_2 with controlled particle size of Pd NPs (17-29 nm) and laid pathway for the effective absorbance of visible matter triggered by the synergetic effect of LSPR. Similarly, a collective oscillation of conduction electrons that were induced by the deposited Ag NPs onto the TiO_2 , drastically enhanced the light absorption of the composite. Moreover these noble NPs also contributed for extending the lifetime of electrons and holes pairs. The study also expressed the variation of these noble metal loading and its influence on the photocatalysis irradiated under artificial visible light. The photocatalysis evaluation studies were performed with lethal and endocrine disrupting compounds (EDCs) of different classification. This includes Amoxicillin for antibiotics and 2, 4-dichlorophenol (2, 4-DCP) for pesticides. Both the composites exhibited an excellent photocatalysis under the artificial visible light with an efficiency of 97.5 % and 63.5 % for removing AMX by Pd/ TiO_2 and Ag/ TiO_2 respectively. In addition the Ag composite also demonstrated similar photocatalysis efficiency for 2, 4-DCP. However the optimal metal

loading for an ideal photocatalysis was found to be 0.5wt% for Pd/TiO₂ and 3.0wt% for Ag/TiO₂. Furthermore in order to enhance the characteristics of the TiO₂ the conducting carbon materials were considered along with the noble metal. The reduced graphene oxide (RGO) a category of conducting carbon was considered for the ternary composite along with Ag. The ternary shown an increased visible light absorption characteristics over the binary composite. This was acknowledged to the intrinsic nature contributed by the RGO. The study also clarified the promotion of electron mobility and prolongation of the lifetime of the charge carriers. This was well correlated with the photocatalysis evaluation achieved through both good and poor photosensitizing pollutants namely Methylene Blue (MB), Reactive Blue 19 (RB19) and Bisphenol A (BPA). The objective was further extended with exploring the prospective Graphitic Carbon Nitride (g-C₃N₄) a semiconductor carbon compound as a visible light enhancer. The wrapping of g-C₃N₄ onto the surface of TiO₂ drastically increased the absorption intensity in-between 390-460 nm and shifted the absorption edge to 460 nm. Subsequently, it well correlated with the photocatalysis efficiency whereby (g-C₃N₄)-Ag/TiO₂ showed the highest photodegradation rate under artificial visible light. Hence, the present studies progressively presented the caliber of the synergisation of conventional photocatalyst to upbeat the limitations and developed a new category of composite photocatalyst. The synthesised photocatalysts well proved their candidature as an active visible light photocatalyst and laid a sustainable pathway for environmental cleanup as demanded by the planet.

ABSTRAK

Tujuan utama tesis ini adalah untuk mengkaji kesan modifikasi yang dibuat terhadap fotokatalis nano titania dalam meningkatkan keupayaan cahaya nampak yang akan digunakan untuk memusnahkan bahan toksik di dalam hidupan akuatik. Pada fasa permulaan, TiO_2 telah berjaya disintesis melalui teknik mudah iaitu “non-hydrolytic sol-gel”. Ciri-ciri kimia membuktikan kehadiran fasa anatase dan penghabluran pada TiO_2 . Ia juga menunjukkan kesan penghabluran terhadap kecekapan fotokatalis. Ini dijelaskan lagi dalam kajian penilaian fotokatalis di bawah sinaran cahaya matahari di mana penghabluran yang tinggi menunjukkan prestasi yang lebih baik. Ciri-ciri yang wujud dalam fotokatalis TiO_2 yang telah disintesis diubahsuai dan ditambahbaikkannya dengan menggabungkannya dengan logam yang lebih baik iaitu “palladium (Pd)” dan “silver (Ag)”. Pengubahsuaian dan penambahbaikkannya telah dicapai melalui kaedah yang sesuai dan ringkas. Penggunaan kaedah baru ini jelas mendedahkan keupayaan cahaya matahari dalam penggabungan logam mulia dan TiO_2 pada saiz yang tertentu iaitu zarah Pd NPs (17-29 nm) dan ia kemudiannya diletakkan untuk penyerapan cahaya nampak dan memberi kesan yang lebih disebabkan oleh kesan sinergi daripada LSPR. Ayunan kolektif elektron konduksi turut terhasil yang disebabkan oleh penggabungan Ag NPs dengan TiO_2 , keadaan ini menyebabkan peningkatan penyerapan cahaya nampak secara drastik. Logam mulia juga melanjutkan hayat elektron dan lubang pasang. Kajian ini menunjukkan perubahan jumlah logam mulia dan kesannya terhadap fotokatalis yang diradiasi oleh cahaya nampak tiruan. Kajian penilaian terhadap fotokatalis telah dijalankan dengan bahan toksik dan sebatian endokrin (EDC) dengan klasifikasi yang berbeza. Ini termasuk “Amoxicillin” untuk antibiotik dan 2, 4-diklorofenol (2, 4-DCP) untuk racun makhluk perosak. Kedua-dua komposit mempamerkan fotokatalis yang baik di bawah cahaya nampak tiruan masing-masing dengan kecekapan 97.5% dan 63.5% bagi menghapuskan AMX oleh Pd/ TiO_2 dan Ag/ TiO_2 . Selain itu, komposit Ag

juga membuktikan kecekapan fotokatalis yang sama bagi 2, 4-DCP. Walau bagaimanapun kapasiti logam yang optimum untuk fotokatalis didapati 0.5wt% untuk Pd/TiO₂ dan 3.0wt% untuk Ag/TiO₂. Selain itu, untuk meningkatkan ciri-ciri TiO₂, bahan-bahan karbon digabungkan bersama-sama dengan logam mulia. “Reduced Graphene Oxide (RGO)” iaitu salah satu jenis karbon telah dipertimbangkan untuk komposit pertigaan bersama-sama dengan Ag. Komposit pertigaan meningkatkan penyerapan cahaya nampak berbanding dengan komposit binari. Ini disebabkan oleh sifat intrinsik yang disumbangkan oleh RGO. Kajian ini juga menjelaskan penggalakan pergerakan elektron dan pemanjangan jangka hayat pembawa cas. Ia berkait rapat dengan penilaian fotokatalis yang dicapai menggunakan bahan pencemar photosensitizing iaitu “Methylene Blue (MB)”, “Reactive Blue 19 (RB19)” dan “Bisphenol A (BPA)”. Objektif kajian telah dikembangkan lagi dengan menerokai bakal “Graphitic Carbon Nitride (g-C₃N₄)” semikonduktor iaitu sebatian karbon sebagai penambah kepada cahaya nampak. Dengan menyaluti g-C₃N₄ pada permukaan TiO₂ secara drastik meningkatkan intensiti penyerapan di antara 390-460 nm dan mengalihkan daya penyerapan sehingga 460 nm. Selain itu, ia juga berkait rapat dengan kecekapan fotokatalis dimana (g-C₃N₄)-Ag/TiO₂ menunjukkan kadar pemfotorosotaan tertinggi di bawah cahaya nampak tiruan. Oleh itu, kajian ini berjaya meningkatkan kebolehan fotomangkin konvensional dan mengembangkan pertemuan baru dalam fotomangkin komposit. Fotokatalis yang disintesis juga membuktikan ianya sebagai fotomangkin cahaya nampak dan dapat digunakan dalam pembersihan alam sekitar.

ACKNOWLEDGEMENTS

During my PhD candidature at University of Malaya for the past three years, I have truly learned great things not just about my academic research but also about life. It is always not an easy riding especially at the beginning of my studies, but I have to mention that I have really enjoyed every single moment of the learning. These experiences painted another important learning chapter in my life that I would never forget. I believe this would not be possible without the help and guidance from each and everyone around me and I would like to take this great opportunity to acknowledge them.

Firstly, I would like to express my greatest gratitude to my supervisor, Dr. Saravanan Pichiah for his endless support and guidance. His positive attitude motivates me to achieve my greatest goal in my research. He gave me countless opportunities which frame and build up my academic career. He is very supportive in many of my new research ideas. I also like to convey my appreciation to my co-supervisor Prof. Dr. Shaliza Ibrahim for her advice and supervision. To my seniors, Dr. Azrina Abdul Aziz who supported me at the early stage of my candidature and Dr. Sim Lan Ching for her advice, discussion and research collaborations.

To all my colleagues, Yee Li, Anis, Chee Ching, Hong Ye, Bee Ling, Aziz, Ranjini, Kien Tek, Sharmini and Shanmuga, thank you for your help and encouragement. Thank you to all the lab assistants, Mdm Kalai, Mdm Rozita and Ms Alya for their supportive assistance and making sure the lab is always in perfect working conditions.

Last but not least to my beloved parents for their kind support and always pray for my success. To my brother and sister, thank you for their never ending words of encouragement. With their unfailing love and support, I could be able to go through all the hardships throughout my PhD candidature.

Thank you all.

CHAPTER 1

INTRODUCTION

1.1 Photocatalysis

Semiconductor photocatalysis has been established as one of the main stream techniques over the last few decades for promising environmental remediation and cleanup. Since 1972, the catalytic ability of Titania (TiO_2) stimulated through photons was first discovered by Fujishima and Honda on their endeavor for water splitting reaction (Fujishima & Honda, 1972). Their discovery has led to a remarkable breakthrough in Advanced Oxidation Process (AOP). This process has proven to be an effective tools in addressing variant environmental problems as compare to those conventional techniques such as adsorption, coagulation, reverse osmosis, ultrafiltration and etc. In recent years, research interest in heterogeneous photocatalysis has been the main focus in environmental applications such as water, wastewater treatment, air purification and etc. This is mainly due to the benefits of heterogeneous photocatalysis such as (i) final oxidation products that are non-hazardous and harmless to the environment (CO_2 , H_2O and other inorganic species), (ii) less formation of secondary pollutants, (iii) uses greener oxidant (O_2), (iv) relatively excited under renewable energy source like natural sunlight in the form of irradiation energy, (v) almost complete degradation or mineralization of pollutants (Ding, Lu, & Greenfield, 2000).

Heterogeneous photocatalysis mainly involves the participation of semiconductor photocatalyst to generate active radicals such as superoxide anions and hydroxyl radicals with the presence of sufficient photon energy. Generally, it consists of

two main steps. First, while the photon energy ($h\nu$) is absorbed by the semiconductor photocatalyst, electrons from the valence band (VB) are promoted to conduction band (CB) leaving behind an equal number of positive holes at the VB. Thus the photogenerated electrons and holes will then migrate to the surface of the semiconductor photocatalyst and react with the strong oxidation and reduction species forming active radicals for oxidation. In the midst most of the electrons and holes tend to recombine and dissipate the energy in the form of heat and light. A simplified mechanism for heterogeneous photocatalysis involving a semiconductor is illustrated in Figure 1.1.

Figure 1.1: Simplified mechanism for photocatalysis involving a semiconductor

1.2 Titania Semiconductor Photocatalyst

In general various potential semiconductors were employed for heterogeneous photocatalysis depending on their band gap energy as illustrated in Figure 1.2. However in particular, TiO_2 has emerged as the most studied semiconductor in environmental applications with high efficiency removal of any organic molecules mainly due to its unconditional benefits. The benefits include; (i) non-toxicity, (ii) chemically and biologically inert, (iii) strong photooxidation power, (iv) natural abundance, (v) low cost and (vi) favourable optoelectronic properties over other equivalent photocatalysts like ZnO , SnO_2 , CdS , ZnS and etc (Ding et al., 2000; Grabowska et al., 2013; R. Su et al., 2011; Yuxin Tang et al., 2012; Z. Wang et al., 2014; Yan et al., 2013; Zhou, Liu, Yu, & Fan, 2012).

Figure 1.2: Band positions of various semiconductors (Gratzel, 2001)

TiO₂ exists in Anatase, Rutile and Brookite crystallographic phases. The difference in crystallographic phases has much influence on the photocatalysis characteristics. Among these phases, anatase and rutile with a tetragonal structure are the most commonly suitable for photocatalysis application (Yan et al., 2013). However, anatase phase outperforms the rutile and emerged as most capable and efficient photocatalyst due to its higher Fermi level and degree of hydroxylation (Carp, Huisman, & Reller, 2004).

1.3 Problem Statements

Although TiO₂ exhibits great photocatalysis by producing hydroxyl and superoxide anion radicals, it also possesses several drawbacks that narrow down its applicability. This includes the wider band gap energy (E_g) of TiO₂ (3.21 eV) (Reyes-Coronado et al., 2008) that restricts its candidature to ultraviolet (UV) region. It is well known that the availability of the UV source is restricted (< 5 %) in the sphere by the ozone layer than that of the visible and infrared (Das & Ghosh, 2013; S. G. Kumar & Devi, 2011; Tong et al., 2012; Z. Wang et al., 2014). In order to promote the environmental sustainability, endless renewable natural source of cleaner fuel, the contemporary Titania must be considered for greater modifications. Next coming back to its recombination characteristics of excited electron (e^-) and hole (h^+) it is always very rapid and suppress the generation of active radicals for photocatalysis reaction (Bumajdad & Madkour, 2014; Leung et al., 2010; Ong, Tan, Chai, Yong, & Mohamed, 2014). This recombination rate was found to be ~30 ns that leads to poor photocatalytic performance (J. Chen, Yao, & Wang, 2008; Chong, Jin, Chow, & Saint, 2010; S. Kim, Hwang, & Choi, 2005). Hence, it is vital to fabricate photocatalysts that possess

enhanced visible light absorption along with prolonged lifetime duration of generated electrons (e^-) and holes (h^+).

Various modifications have been practiced to overcome the shortfalls of TiO_2 photocatalyst through doping with metals and non-metals (Pan, Yang, Fu, Zhang, & Xu, 2013; D.-H. Wang, Jia, Wu, Lu, & Xu, 2012; Xiang, Yu, & Jaroniec, 2011), mashing with other semiconductors (Karunakaran & Gomathisankar, 2013; G. Li, Zhang, & Jimmy, 2009; M. Li et al., 2013; Yajun Wang et al., 2013b), incorporation of carbonaceous materials like graphene, activated carbon and carbon nanotubes (Ong, Gui, Chai, & Mohamed, 2013; L. Sun, Zhao, Zhou, & Liu, 2012; Y. Zhang, Tang, Fu, & Xu, 2011). However, recent innovation on improvisation to TiO_2 photocatalyst had benefited to overcome its limitations.

Noble metals, recognized as a new category of efficient agent or dopant to stimulate the visible light utilization due to their higher optical absorption in visible spectrum. They demonstrate a localized surface plasmon resonance (LSPR) phenomenon that allows their interaction, promotes and maximize light absorption in the visible region. Besides that, the formation of Schottky junction between the noble metal and semiconductor prolong the lifetime of the generated charge carriers. On top of it, they can function as effective co-catalysts to reduce the over potential for surface electrochemical reactions (Qu & Duan, 2013).

On the other hand the recent development and domination of the carbonaceous elements attracted the photocatalysis researchers as well. The RGO finds a greater application owing to its unique characteristics that facilitates the bonding of Ti with C. (Tan, Ong, Chai, & Mohamed, 2013; Umrao et al., 2014). Apart from it the polymeric semiconductor graphitic carbon nitride (g- C_3N_4) also plays a vital role due to its exclusive properties of good physicochemical stability and an appealing electronic

structure combined with a medium band gap (2.7 eV). Thus demonstrating their necessity as potential agent for enhancing and modifying the characteristics of conventional TiO₂ (Sridharan, Jang, & Park, 2013; L. Zhang et al., 2014).

1.4 Objectives and Scope of Research

The key scope of the present study is to top down the identified limitations of the conventional titania by incorporating the most active noble metals (Pd and Ag) to trigger the surface plasmon resonance characteristic and form a classification called “*plasmonic photocatalysts*”. In addition, conducting carbon materials such as reduced graphene oxide (RGO) was wrapped with TiO₂ together with noble metals to further enhance the visible light absorption and promote the charge carrier transportation. Apart, the photocatalytic ability is also examined by incorporating with a ternary metal free semiconductor (g-C₃N₄). The visible light photocatalysis ability of the synthesized nanocomposite photocatalysts were evaluated by degrading variant genera of pollutants that include Endocrine Disrupting Compounds (EDCs) and Dyes under solar and artificial visible light source. Overall the studies presented new insights in the modification of the TiO₂ that enhances the visible light absorption and lead to a better photocatalytic activity performance. The objectives of the work are as follows:

- **Synthesis of Template:** To synthesize highly pristine anatase TiO₂ nanoparticles (NPs) as template through a simple, facile and ease method.
- **Inclusion of Plasmonic Phenomenon:** To identify suitable noble metals from the periodic table along with a novel, smart, ease and sustainable method to incorporate them onto TiO₂ template for activating Localized Surface Plasmon Resonance (LSPR) Phenomenon and identifying the optimum loading of noble metals.

- **Electron Mobility Promoter:** To investigate the contribution of carbon materials for visibility, electron mobilizing and charge carriers' transportation by wrapping it onto the synthesized composite photocatalysts.
- **Dissection of Photocatalysts:** To characterize the prepared nanocomposite photocatalysts for its various intrinsic natures through crystalline phase analysis, morphology, elemental composition, surface area and pore size characteristics, chemical composition with electronic state, Raman scattering, optical and photoluminescence properties.
- **Assessment of Visible Light Performance:** To evaluate the visible light photocatalysis ability of the synthesized nanocomposite photocatalysts by adopting various categories of simulated EDC and Dye pollutants.

1.5 Report Overview

Chapter 1 presents the introductory note on photocatalysis process and semiconductor titania. This is followed by problem statement together with specific research hypotheses. The chapter ends with identified specific objectives for resolving the research hypothesis.

Chapter 2 outlines the comprehensive report on the literatures. It elaborates the clear background on heterogeneous and semiconductor photocatalyst (TiO_2). Besides that, it also elaborates on the synthesis method and modifications of TiO_2 which lead to enhance visible light absorption and suppress the recombination rate of electron and hole pairs. It also reviews the environmental applications of prepared photocatalyst in degradation of variant toxic and lethal liquid pollutants.

Chapter 3 discusses on the adopted precursor, solvents and synthesis method for obtaining synergized modified photocatalysts. The chapter also narrates on the various experimental conditions, analytical methods practiced for characterizing the synthesized photocatalysts and quantifying the studied pollutants.

Chapter 4 presents the results of the adopted research hypotheses. This chapter unveils the materials chemistry of the prepared photocatalysts and its versatility in utilizing the visible light with its mechanism. The chapter also substantially discusses on the photocatalysis excellence demonstrated by the prepared materials towards visible light driven environmental cleanup applications.

Chapter 5 summarizes the entire significant outcome of the thesis and recommendations for the continuation of the current studies.

CHAPTER 2

LITERATURE REVIEW

2.1 Heterogeneous Photocatalysis

Heterogeneous photocatalysis a classification of Advanced Oxidation Processes (AOPs) plays a major role in Environmental Nanotechnology and is recognized as one of the “foundation pillars” of green chemistry (Anastas, Kirchhoff, & Williamson, 2001). In general catalyst is defined *as a substance that can accelerates a chemical reaction without being consumed as a reactant*. Meanwhile, photocatalyst is defined *as the acceleration of a reaction by the presence of a catalyst through photon energy*. Over the past decades, the application of this photocatalysis concept has proven to be promising in solving many major environmental and energy concerns like toxic organics pollutants degradation, water split reaction for hydrogen production and CO₂ reduction.

The heterogeneous photocatalysis involves the presence of a semiconductor photocatalyst to initiate or accelerate specific redox reactions (reduction and oxidation). A schematic illustration of the principle of semiconductor photocatalysis is shown in Figure 2.1. When this semiconductor photocatalyst is illuminated with photon energy which is equal or greater than their band gap energy, electrons and holes are generated in the valence band (Figure 2.1(I)). Moreover, with sufficient energy, the electrons (e⁻) are excited from valence band to conduction band leaving behind positive holes (h⁺) (Hoffmann, Martin, Choi, & Bahnemann, 1995). Thus excited electrons and formed holes migrate to the surface and perform the redox reactions. The electrons from the conduction band possess chemical potential of +0.5 to -1.5 V versus the normal hydrogen electrode

(NHE) and reveal a strong reduction capacity (Figure 2.1(III)). Meanwhile, the holes in the valence band possess chemical potential of +1.0 to +3.5 V versus the NHE and exhibited a strong oxidative potential (Figure 2.1(IV)). Thus photogenerated electrons and holes facilitates the robust redox reaction. The electron donors or electron acceptors are adsorbed on the surface of semiconductor and produces active radical, responsible for the degradation of pollutants (Figure 2.1(V)) (H. Wang et al., 2014).

During the photocatalysis, recombination of excited electrons with the holes are forced and dissipates the input energy in the form of light or heat (Figure 2.1(II)). This recombination phenomena occurs due to the scavenger or crystalline defects and able to trap the electrons and holes. Based on the fundamental of semiconductors photocatalyst principles, this phenomenon heavily hinders the photocatalytic efficiency.

Figure 2.1: Schematic illustration of semiconductor photocatalysis principle (H. Wang et al., 2014)

Numerous advantages that heterogeneous photocatalysts can offer are such as (i) enrich the semiconductor light absorption ability by incorporating with metal/non-metal, other semiconductors and noble metal (ii) improving the charge separation efficiency by forming a Schottky junction (metal/semiconductor heterostructures) with built-in electrical potential or p-n (semiconductor/semiconductor heterostructures) (iii) integration with a suitable cocatalyst can lower the redox over potential at the relevant active sites (Qu & Duan, 2013).

2.2 Semiconductor Photocatalyst (TiO₂)

Over the past years, interest in the application of semiconductor photocatalyst has grown tremendously attracted the environmental engineers for a full-fledged treatment of liquid and gaseous waste. These semiconductors (TiO₂, ZnO, Fe₂O₃, CdS and ZnS) embrace electronic structure of completely filled valence band and empty conduction band. The electronic structure endorses as sensitizers for light reduced redox processes (Hoffmann et al., 1995). Among the many semiconductors, TiO₂ turn out to be the most attractive and promising semiconductor as photocatalyst. This was owing to its superficies, versatile and unique characteristics that allow concurrent oxidation of water and reduction of protons. The innovative feature of TiO₂ was first identified by Honda and Fujishima in 1972 where they discovered a photosensitization effect of TiO₂ electrode for electrolysis of water into H₂ and O₂ upon applying an external bias (Fujishima & Honda, 1972). Further it also exhibits merits including non-toxicity, chemical and biological inert, photostability, high photoactivity and economical (Ding et al., 2000; Grabowska et al., 2013; R. Su et al., 2011; Yuxin Tang et al., 2012a; Z. Wang et al., 2014). Thus designate TiO₂ photocatalyst as potential candidate for various environmental and energy remediation.

It is well known that this photocatalyst exists in three crystalline phase i.e., anatase, rutile and brookite. The structures of these are depicted in Figure 2.2 and crystal data is tabulated in Table 2.1. Both the anatase and rutile exhibited tetragonal crystal structures and the distortion of cubic lattice is more significant for anatase resulting in a less orthorhombic symmetry than rutile (Nick Serpone & Pelizzetti, 1989; Thompson & Yates, 2006). It also possess higher Fermi level and degree of hydroxylation that makes its more active in driving photoreaction than the other phases (Carp et al., 2004; Hyun & Kang, 1996; Kermanpur, Ghassemali, & Salemizadeh, 2008; Samuneva, Kozhukharov, Trapalis, & Kranold, 1993). Besides rutile phase shows high recombination rate of electron-hole pairs and very low density of superficial hydroxyl groups that limits its photocatalytic reaction (Choi, Termin, & Hoffmann, 1994; Sclafani & Herrmann, 1996).

Figure 2.2: Crystalline structure of TiO_2 (a) Anatase, (b) Brookite and (c) Rutile (Khataee & Kasiri, 2010)

Table 2.1: Crystal structure data for various phase of TiO₂ (Baur, 1961; Cromer & Herrington, 1955)

	Anatase	Rutile	Brookite
Crystal structure	Tetragonal	Tetragonal	Orthorhombic
Lattice constants (Å)	$a = 3.784$	$a = 4.5936$	$a = 9.184$
	$c = 9.515$	$c = 2.9587$	$b = 5.447$
			$c = 5.145$
Space group	$I4_1/amd$	$P4_2/mnm$	$Pbca$
Molecule/cell	4	2	8
Volume/molecule (Å ³)	34.061	31.216	32.172
Density (g/cm ³)	3.79	4.13	3.99
Ti – O bond length (Å)	1.937 (4)	1.949 (4)	1.87 ~ 2.04
	1.965 (2)	1.980 (2)	
O – Ti – O bond angle	77.7°	81.2°	77.0° ~ 105°
	92.6°	90.0°	

The applications of semiconductor nanomaterial are much dependent on the preparation method and greatly influenced by the size and morphology also. Therefore various synthesis methods such as sol-gel process (Hench & West, 1990; Hou, Hung, et al., 2011; Rodríguez-González, Zanella, del Angel, & Gómez, 2008), hydrothermal and solvothermal process (Humin Cheng, Ma, Zhao, & Qi, 1995; Yoshimura & Byrappa,

2008; S. Zhu et al., 2012) and deposition methods (Lee & Tu, 2008, J.-J. Wu & Tseng, 2006) have been practised. Synthesis through sol-gel method has dominated over the rest due its facile nature in achieving TiO₂ with high purity and superior compositional homogeneity (Stoyanova et al., 2010).

2.3 Sol-Gel Synthesis

Sol-gel route is mostly considered in synthesis of pristine anatase TiO₂ because it provides compositional and microstructural modification through controlling the precursor and the governing synthesis parameters. It also delivers superior chemical homogeneity, unique metastable structures and high purity (Niederberger, Bartl, & Stucky, 2002; C.-C. Wang & Ying, 1999). However, most of the cases the chemical reactions rate are very fast especially with transition metal precursors, making it difficult to control the chemical process. This could be the major limitation of sol-gel method where a minor modification in the synthesis parameter could lead to a drastic change in structure and morphology of the nano photocatalyst (Stoyanova et al., 2010). In order to outwit this limitation and secure the benefits of sol-gel synthesis method, non-hydrolytic sol-gel method was developed (Djerdj, Arčon, Jagličić, & Niederberger, 2008; Vioux, 1997). This synthesis is performed in an organic solvents in the absence of water lead to a slower reaction rate and provides better control over the particle size and crystallinity (Niederberger & Garnweitner, 2006).

In synthesis of TiO₂ using non-hydrolytic sol-gel method, it usually involves the reaction of titanium chloride (or alkoxide) with different oxygen donor molecules such as alcohol, ether, aldehyde or ketone. The condensation between Ti – Cl and Ti – OR, results in the formation of Ti – O – Ti where the alkoxide functions can be provided by titanium alkoxides or can be formed in situ by reaction of titanium chloride with oxygen

donors (Niederberger et al., 2002). Hence, this facile synthesis method results in the formation of pristine anatase TiO₂.

2.4 Modification of Titania

The candidature of TiO₂ has been studied extensively for three decades due to their incomparable qualities. However, they have few major drawbacks on its photoexcitation domain: (i) wide band gap energy 3.2 eV (ii) higher recombination rate of photogenerated electrons and holes and (iii) low absorption ability in the visible light region. All these limitations hinder its inherent photocatalytic characteristics especially in the visible light region. Therefore, remarkable effort has been dedicated to overcome all these limitations especially in utilizing the abundant renewable energy (solar energy), ~43.0% of visible light as compare to <5.0% of UV light. Hence, it is important to design a photocatalyst that can effectively extend the light absorption spectra to visible region in order to enhance the harvesting of solar energy. Besides that, further modification necessitates the minimisation of recombination rate of electrons and holes in order to enhance the redox reaction.

Tremendous modification methods through doping or composite with metal or non-metal (Xiang, Yu, & Jaroniec, 2011; Xiang, Yu, Wang, & Jaroniec, 2011; J. Yu, Xiang, & Zhou, 2009), coupling and construction of heterojunctions (Hefeng Cheng et al., 2013; K. Su, Ai, & Zhang, 2012; Zeyan Wang et al., 2009), integration with carbonaceous material (Ong et al., 2013; L. Sun et al., 2012) and plasmonic photocatalyst (Hou, Liu, Pavaskar, Hung, & Cronin, 2011; Lou et al., 2011; Peng Wang et al., 2011; F. Xiao, 2012b) had been executed by various researchers. Off these, plasmonic photocatalyst emerged as the best and overshoots the limitations of other modification methods. The notable drawbacks of these methods were listed below. The non-metal

doping promotes production of oxygen vacancies that act as a recombination center for electrons and holes. Similarly, metal doping lead to the formation of defects inside TiO_2 which reduces the photoreactivity (Nagaveni, Hegde, & Madras, 2004; Xu, Gao, & Liu, 2002). Therefore, by decorating noble metal onto semiconductor spinal had proven to trigger the localized surface plasmon resonances phenomena (LSPR) for better visible light photocatalytic activities.

2.5 Plasmonic Photocatalyst

A combination of noble metal and semiconductor photocatalysts form a unique “*Plasmonic photocatalyst*” classification. Recently, plasmonic photocatalysts have been proven to yield high photocatalytic performance due to its inherent contributions to the semiconductor photocatalyst and results in enhanced wide range of light absorption, suppressed electron-hole recombination rates, increased photogenerated electron-hole pairs and improved the redox reactions rates (Z. Wang et al., 2014). The distinct characteristics features contributed by the plasmonic photocatalysis are illustrated in Figure 2.3.

Noble metals (i.e Ag, Au, Pd, Pt) in nanoparticles form acknowledge as new impurity agent for harvesting visible light energy due to their high optical absorption over a wide range of the solar spectrum (Cushing et al., 2012; Linic, Christopher, & Ingram, 2011). This strong absorption of light energy in visible region is due to its own characteristic of surface plasmon resonance (SPR) effect. The surface plasmon band is a robust and broad band in the visible spectrum of metallic nanoparticles possessing size $> 2 \text{ nm}$ (Shin et al., 2010). The intensity of the surface plasmon band is much dependent on the size, shape, monodispersity, dielectric constant of surrounding medium, electronic interactions between stabilizing ligands and nanoparticles (Moores & Goettmann, 2006).

Besides, when these nanoparticles interact with semiconductor it promotes Schottky junction a unique feature of noble metals. This Schottky formation contributes for reduction in recombination rates of electron-hole pairs (Zhichao Wang, Liu, & Chen, 2012).

Figure 2.3: Major benefits of plasmonic photocatalysis (X. Zhang, Chen, Liu, & Tsai, 2013)

The Localized Surface Plasmon Resonance (LSPR) of a noble metal NPs arises when it's being induced by the oscillating electric field of the imposing light. During the oscillation the photon frequency ties with the natural frequency of the noble metal leading to decline in electrons to one side of the noble metal NPs and surge on the other side of the surface. This phenomenon will cause the redistribution of the charge density and thus create an electric field inside and outside of the noble metal NPs in opposite direction.

Therefore a coulombic restoring force is then established and the conducting electrons of the noble metal NPs will then undergo a harmonic oscillation in phase with the incident light (Sarina, Waclawik, & Zhu, 2013; C. Wang & Astruc, 2014; Peng Wang, Huang, Dai, & Whangbo, 2012; Zhou et al., 2012). This oscillating charges excites electric field near the surface and once the frequency is adequate with the resonance of the noble metal, SPR is triggered, leading to the active absorption of visible light (Figure 2.4 (a)). This absorption visible spectrum promoted through SPR is attributed to the electric polarization effect. In addition, SPR on noble metal accelerates the electron transfer from the photoexcited noble metal to any polar semiconductor (P. Wang et al., 2012).

Figure 2.4: (a) Schematic of SPR in a noble metal particle that is illuminated by light (Kelly, Coronado, Zhao, & Schatz, 2003). (b) Surface plasmon decay processes (Clavero, 2014)

The plasmon excitation decaying processes play a crucial role and that determine the photocatalytic efficiency of plasmonic photocatalyst. It entails depositing energy into the absorbates through different pathways and transferring energy from the plasmonic metal NPs to any polar semiconductors (Kale, Avanesian, & Christopher, 2014). There are two major pathways for the occurrence of oscillation of electron decay either through radiative or non-radiative (Figure 2.4 (b)). The radiative process results in scattering of light effect and dominated by larger particle size (≥ 40 nm). Meanwhile the non-radiative decay process is mainly governed by smaller one and will enhance the absorption resulting in the excitation of energetic electrons and holes (C. Wang & Astruc, 2014). In noble metal this non-radiative decay occurs through intraband excitations within the conduction band or through interband excitations resulting from transitions between other bands and conduction band.

Figure 2.5: The corresponding resonant wavelength for metallic nanoparticles of 10 nm (Garcia, 2011)

The surface plasmon resonance frequency strongly influences various parameters of the noble metals and it includes particle size, shape, interparticle interactions and local dielectric environment (Galian & Perez-Prieto, 2010; Haruta, 2005; Palmisano et al., 2010; Stahl, 2005). It is also to be noted that not all noble metal with the particles size 10 nm are capable to absorb light in the visible region as shown in Figure 2.5. Most commonly, Ag and Au NPs are in favour to absorb photon energy with a relative strong excitation in the visible regime. Moreover, these two noble metals possess a characteristic of producing a stable high charge carrier density (Boltasseva & Atwater, 2011). However, cost of Ag makes it more appropriate to be used for wider applications. Hence, many studies had been reported by other researchers on using Ag as plasmonic materials (Choi, Shin & Jang, 2010; Xiang et al., 2010; Xie et al., 2011). Where else, palladium NPs with smaller size are restricted to UV spectrum. However, larger particle and clustered size overdrawn the restriction by well absorbing in the visible light regime. This was demonstrated by Mohapatra and coworkers where they successfully achieved the visible light enhancement for the Pd NPs in range of ~80 nm in diameter (Mohapatra, Kondamudi, Banerjee, & Misra, 2008). Similar findings were observed by Kwak et al by incorporating Pd NPs (~15 nm) onto TiO₂ leading to an increase absorption in visible spectrum (Kwak, Chae, Kim & Kang, 2009).

The mechanism of plasmon-assisted physics is of great interest in understanding the generation and injection of excited electrons. When photon energy is absorbed, free electrons of metal NP occupy higher energy level. Considering a single electron, the excitation will take place at lower Fermi level (E_f), producing a constant distribution of primarily excited electrons at energy level between E_f and $E_f + h\nu$ (Kale et al., 2014). This excited electron losses its energy readily right after the primary plasmon excitation through electron-electron relaxation within ~ 10 fs through non-equilibrium Fermi-Dirac electron distribution (Molina, Weinmann, & Jalabert, 2002). In this energy redistribution

process, excited electron is transferred from the metal NPs to the semiconductor and it fully dissipates the electron in the semiconductor (Kochuveedu, Jang, & Kim, 2013). These phenomena of equilibration of the E_f will cause a bending of the semiconductor conduction band and form a Schottky barrier that prevents electron transfer from the metal to the semiconductor. The excited electrons with energies higher than the Schottky barrier are injected into the nearby semiconductor through the SPR decay effect (White & Catchpole, 2012). The plasmonic nanostructures will then leave positively charged holes due to electron depletion. Thus generates holes undergo electron-donor process or transporting generated holes to the counter electrode in order to prevent the recombination (Clavero, 2014). Figure 2.6 (a) shows the excitation of electron from the thermal equilibrium to higher energy state upon photons irradiation. While in Figure 2.6 (b) illustrates the collision prompted a formation of Fermi Dirac distribution at a high temperature Fermi level due to redistribution of electron energy. Figure 2.6 (c) portrays the excited electrons flow back to the standard distribution meanwhile in the semiconductor electrons and holes flow to different regions (Kochuveedu et al., 2013; X. Zhang et al., 2013).

Figure 2.6: Illustration of Surface Plasmon Resonance principle (Kochuveedu et al., 2013; X. Zhang et al., 2013)

The formation of Schottky barrier is another unique characteristic of plasmonic photocatalysts. This formation is created when a metal and a semiconductor interact with each other (Figure 2.7). Electrons will flow from higher Fermi level to the lower in order to align the energy level at the interface of the metal and semiconductor. This equilibrium of Fermi level creates a built-in electric field at the interface which will promote the charge separation of photogenerated electrons and holes by forcing the electrons and holes to move in different directions (Bumajdad & Madkour, 2014; Qu & Duan, 2013; Jian Tian, Zhao, Kumar, Boughton, & Liu, 2014; H. Wang et al., 2014).

Figure 2.7: Schematic of the Schottky barrier (H. Wang et al., 2014)

2.6 Preparation of Plasmonic Photocatalysts

There are numerous synthesis method adopted or practiced to prepare plasmonic photocatalysts. Some of them are photoreduction (Kominami, Tanaka, & Hashimoto, 2010, 2011; Sung-Suh, Choi, Hah, Koo, & Bae, 2004; Xie, Kum, Zhao, & Cho, 2011), ion-exchange (Hefeng Cheng et al., 2011; Peng Wang, Huang, Lou, et al., 2010; Peng Wang, Huang, Zhang, et al., 2010), deposition-precipitation (Gomes Silva, Juárez, Marino, Molinari, & García, 2010; Peng, Hu, Hu, Zhou, & Qu, 2012; Hui Zhang, Fan, Quan, Chen, & Yu, 2011), chemical reduction (Christopher, Xin, & Linic, 2011; Ingram & Linic, 2011; Nair, Tripathi, & Samdarshi, 2011), hydrothermal (S. Sun, Wang, Zhang, Shang, & Wang, 2009; Xiang, Yu, Cheng, & Ong, 2010), physical vapour deposition (Hou, Liu, et al., 2011; Z. Liu, Hou, Pavaskar, Aykol, & Cronin, 2011), impregnation (H. Yu, Liu, Wang, Wang, & Yu, 2012; Zheng et al., 2011) and encapsulation (Thomann et al., 2011; Torimoto et al., 2011). The various preparation methods of plasmonic photocatalysts along with its photocatalysis performance are tabulated in Table 2.2.

Table 2.2: Photocatalysis performance of various plasmonic photocatalysts along with its preparation method

Composite photocatalyst	Preparation method	Photocatalytic experiment & Photocatalysis performance	Reference
TiO ₂ -Ag	Polyol process	Photodegradation of Methylene Blue (0.65 mM) under UV light irradiation. Ag cubes TiO ₂ exhibited a better photo degradation as compare to other shapes such as wires and spheres.	Christopher, Ingram & Linic, 2010

Table 2.2, continued

Composite photocatalyst	Preparation method	Photocatalytic experiment & Photocatalysis performance	Reference
TiO ₂ -Ag	Polyol process	Photodegradation of Methylene Blue (0.65 mM) under UV light irradiation. Ag cubes TiO ₂ exhibited a better photo degradation as compare to other shapes such as wires and spheres.	Christopher, Ingram & Linic, 2010
Ag-TiO ₂	Microwave hydrothermal	Photodegradation of RhB under $\lambda > 420\text{nm}$. The prepared Ag-TiO ₂ nanocomposite hollow spheres exhibited highest photocatalytic activity by a factor of more than 2 compare to pure TiO ₂ and commercial Degussa (P25).	Xiang et al., 2010
Ag-TiO ₂	Photo deposition	Degrading Rhodamine B under visible light with an initial concentration of 10^{-5} M. Ag-TiO ₂ with 2% Ag content was found to be the optimum loading and achieved highest efficiency with ~30% increase in photo degradation as compare to TiO ₂ .	Sung-Suh et al., 2004
Ag/TiO ₂	Electrochemical deposition	Photocatalytic degradation of Methyl Blue (2×10^{-5} M) illuminated with light intensity $> 420\text{ nm}$. Ag/TiO ₂ achieved about 80% removal in 2.5 h as compare to pure TiO ₂ .	Z. Chen et al., 2014
Ag-TiO ₂	Sol-gel process	Photodegradation of Indigo carmine under visible light with an initial concentration of 2.5×10^{-5} M. Ag modified TiO ₂ showed great photocatalysis performance where it achieved a complete removal after 3 h as compare to pure TiO ₂ .	Suwanchawali t, Wongnawa, Sriprang, & Meanha, 2012

Ag@TiO ₂	Photo reduction by artificial UV light	Photodegradation of Rhodamine B irradiated under visible light. Ag@TiO ₂ with an optimal catalyst loading of 1% of Ag shown a complete degradation in 30 min with an initial dye concentration of 10 mgL ⁻¹ .	D. Chen et al., 2013
Ag/AgCl	In situ oxidation process	Photodegradation of Methyl Orange and 2, 4 dichlorophenol under visible light irradiation. AgCl with the ratio of 85% revealed the best photocatalytic performance in degrading both the pollutants where an efficiency of 65% (Methyl Orange) and 78% (2, 4-dichlorophenol) was achieved	Jia, Yang, & Huang, 2014
Ag-AgCl	Hydrothermal	Decomposition of Methyl Orange under visible light with an initial concentration of 10 mg/L. It achieved almost a complete removal in 18 min.	Han, Wang, Zhu, Zhai & Dong, 2011
Ag-AgCl	Precipitation of AgCl followed by reduction	Photodegradation of Methyl Blue under visible light and sunlight with an initial concentration of 20 mg/L. It shows a great enhancement under sunlight with a complete removal in 30 min.	An, Peng & Sun, 2010
Ag-AgBr	Light induced chemical reduction	Degrading Methyl Orange (20 mg/L) under visible light illumination. A complete degradation was obtained after irradiation for 10 min.	Wang et al., 2009
Au-TiO ₂	Electrochemical-evaporation	Water splitting under visible light irradiation. After the addition of Au nanoparticles, it observed a drastic enhancement in the photocatalytic splitting of water	Liu et al., 2011

Table 2.2, continued

TiO ₂ -Au	Deposition precipitation	– Photocatalysed reduction of nitrobenzene (1×10^{-3} M) and photooxidation of alcohols (5×10^{-4} M) under UV and visible light respectively. TiO ₂ -Au/anatase showed a higher UV light activity for the reduction of nitrobenzene than TiO ₂ -Au/rutile. Meanwhile TiO ₂ -Au/rutile showed an increase in visible light activity for the oxidation of alcohols.	Kimura, Naya, Jin-nouchi & Tada, 2012
Au@TiO ₂	Deposition-precipitation-photoreduction	Oxidation of benzene (0.07 mL) under visible light irradiation. Au@TiO ₂ yielded about 61% of benzene was oxidized to phenol after 3 h of irradiation.	Zheng et al., 2011
Pd/TiO ₂	Incipient wetness	Photo degradation of azo dyes under visible light with an initial dyes concentration of 0.024 mM. A complete removal was attained in 150 min (Methyl Red) and 270 min (Methyl orange) by Pd/TiO ₂ .	Mohapatra et al., 2008
Pt-TiO ₂	Deposition-precipitation	Oxidation of benzyl alcohols (100 mg/L) to aldehydes under visible light source. After 3 h of visible light irradiation, Pt-TiO ₂ shows about 90% conversion of alcohols as compared to pure TiO ₂ .	Zhai, Xue, Zhu, Luo & Tian, 2011

2.6.1 Photoreduction

Among the synthesis methods, photoreduction method had defeated the rest due to its relatively high deposition ratio and low aggregation (Zhou et al., 2012). This preparation method is simple and eases where it delivers high quality plasmonic photocatalysts. This process involves the efficient anchoring of noble metal onto the

semiconductor with the presence of photon energy. Semiconductors like TiO₂, ZnO and etc possess a unique electronic structure where it composes of filled valence band (VB) and empty conduction band (CB). When the semiconductor is irradiated with adequate photon energy (photon energy that exceeded its band gap energy), it generates electrons and holes at the valence band. This further excites the electrons from the valence band to the conduction band leaving behind the positive charge holes. The generated photoexcited electrons can interrelate with any ionic metal species to produce metallic NPs onto the support materials where else the holes at the valence band reacts with sacrificial scavenger. The schematic representation of photoreduction method is illustrated in Figure 2.8

Figure 2.8: Schematic illustration of photoreduction synthesis method

The foremost advantage is that it possesses a high deposition ratio of noble metal onto the semiconductor surface. Kowalska et al., successfully deposited Au onto TiO₂ surface to form Au/TiO₂ under UV irradiation (Kowalska, Abe, & Ohtani, 2009). Meanwhile, Tanaka et al., also successfully synthesized Au/CeO with a large deposition

ratio (> 99.9%) under UV light illumination (Tanaka, Hashimoto, & Kominami, 2011). The last one is it never requires further calcination as expected in other synthesis methods. The elimination of this calcination step reduces the aggregation of particles leading to high yield and homogeneously deposition of noble metal onto the semiconductor.

In most cases an artificial UV light is being used as the source of photon energy for photoreduction method. But the high demand on sustainable and green approach in today context had driven us to look into a more renewable source of energy to replace the artificial UV light. Natural sunlight is an agent of sustainable choice for “green” chemical synthesis due to its abundance availability, environmentally friendly and economical. Therefore, utilizing the photon energy delivered by the natural sunlight could be a best replacement for artificial UV light. The supplied photon energy drives many photoreactions and encourages the reduction and deposition of noble metal onto any polar semiconductor to form plasmonic photocatalysts and support the sustainable route. This approach was successfully adopted in the presented study.

2.7 Carbon Material

Carbon nanomaterials applications in catalysis are well known and continue to grow for the past years. This type of nanomaterials is most commonly used either as support for immobilizing active species or as metal-free catalysis (Machado & Serp, 2012). There are few types of carbon nanomaterials like fullerenes, carbon nanotubes and graphene. Graphene a recent innovation had attracted great attention due to its versatile and diversified applications. It is a flat single layer of sp^2 -bonded carbon atoms firmly packed into a two-dimensional honeycomb lattice (Jingqi Tian et al., 2012). It possesses distinctive electronic, optical, thermal and mechanical characteristics that had great influence in photocatalysis. Their numerous unique characteristics include: large specific

surface area, outstanding thermal conductivity, high hydrophobicity, great adsorption capacity, high mobility of charge carriers and high optical transmittance (J. Liu, Tang, & Gooding, 2012; Machado & Serp, 2012; Yanhong Tang et al., 2012b; Jingqi Tian et al., 2012; Xiang, Yu, & Jaroniec, 2012; N. Zhang, Zhang, & Xu, 2012).

There are wide ranges of synthesis techniques for producing this graphene and can be classified into two different method namely “bottom-up” and “top-down” method. In bottom-up methods, the graphene is synthesized by chemical reaction through atoms or molecules (Xiang et al., 2012). The notable examples will be the growth on a single crystal SiC and chemical vapor deposition on metal foil surfaces (Juang et al., 2010; K. S. Kim et al., 2009; Wei et al., 2009). However these synthesis methods are not widely practiced due to its own complexity, limited scaling-up and high cost of precious metal substrates (Xiang et al., 2012). Therefore top-down methods such as thermal exfoliation (McAllister et al., 2007), electrostatic deposition (Tung, Allen, Yang, & Kaner, 2008) and chemical exfoliation of graphite (Dan Li, Müller, Gilje, Kaner, & Wallace, 2008; Park et al., 2009) are adopted for obtaining superior graphene. These top-down methods give rise to low cost, facile preparation process and larger yield as compare to bottom-up methods.

2.7.1 Chemical Exfoliation of Graphite

This is one of the most commonly used techniques in preparing high quality graphene and usually adapting the Hummers’ method (Hummers Jr & Offeman, 1958). The reduced graphene oxide (RGO) in this method was achieved by oxidation of nature graphite powder with strong chemical oxidants like KMnO_4 , HNO_3 and H_2SO_4 . The obtained graphene oxide (GO) is then washed and dialysed to eliminate unnecessary inorganic impurities (residual ions and acids) through centrifugation. During the exfoliation of GO sheets, it normally possesses a rich assortment of oxygen containing

groups (carboxylic, hydroxyl, epoxide functional groups) that allows the interactions with cations and further produces a reactive site. This reactive site is responsible for the rapid growth and nucleation of nanoparticles to various graphene based composites. Furthermore GO can also be reduced with fractional restoration of the sp^2 -hybridized by either sonochemical (Vinodgopal et al., 2010), microwave reduction (Jasuja, Linn, Melton, & Berry, 2010), electrochemical (Ramesha & Sampath, 2009), photo thermal (Abdelsayed et al., 2010) or chemical method (Gao, Jang, & Nagase, 2009). A schematic of typical preparation of reduced graphene oxide by chemical reduction (Hummers' method) is depicted in Figure 2.9.

Figure 2.9: Schematic of preparation of reduced graphene oxide by chemical reduction (Hummers' method) (Bai, Li, & Shi, 2011)

2.7.2 Preparation of Graphene based Semiconductor Photocatalysts

The graphene based semiconductor photocatalysts are prominently obtained through in situ growth (Lambert et al., 2009), hydrothermal/solvothermal (Fu & Wang,

2011), solution mixing method (Akhavan & Ghaderi, 2009). Off them the hydrothermal technique is one of the traditional and an effective method for incorporating graphene into semiconductors. This simple process involves the incorporation of semiconductor composite onto the graphene sheets and reduces to graphene. During the hydrothermal reaction process, GO is reduced to graphene and simultaneously loaded onto the semiconductor composite. Table 2.3 detailed the various studies on RGO incorporating with TiO_2 and noble metal.

Table 2.3: Summary of literature studies of conducting carbon materials as composite for photocatalysts

2.8 Graphitic Carbon Nitride

Apart from the RGO metal free polymeric semiconductor, graphitic carbon nitride (g-C₃N₄) had very recently attracted tremendous attention of researchers for a robust and stable visible light driven photocatalyst. As compared to other inorganic semiconductor, g-C₃N₄ consists mainly of carbon and nitrogen which are among the most abundant elements in our planet, making it a sustainable and environmentally organic semiconductor. The heptazine ring structure and the high condensation degree enable this metal free semiconductor to have various notable advantages such as good physicochemical stability, harvesting visible light with a band gap of 2.7 eV, suitable redox potential to efficiently catalyze reactions, abundant, and inexpensive. These unique properties make g-C₃N₄ a promising candidate for visible light enhancement. Nevertheless, pure g-C₃N₄ suffers from shortcomings such as rapid recombination rate of photo-generated electron-hole pairs and a small specific surface area. However, its 2-dimensional layered structure enables it for hybridizing with other component to overcome its shortcomings.

Most commonly g-C₃N₄ is prepared by simple route by adopting nitrogen rich organic molecules as single source precursors under thermal treatment. Zou *et al.*, reported a direct heating of melamine to g-C₃N₄ in a semi-closed system (Yan, Li, & Zou,

2009). J. Zhang *et al.*, uses the thermal polycondensation of cyanamide or dicyandiamide into g-C₃N₄ with a continuous flow of N₂ gas (J. Zhang et al., 2010). Meanwhile, Lotsch and Schnick employed the thermal transformation of guanylurea dicyanamide to g-C₃N₄ that enable it to render more oxygen containing organic compound (Lotsch & Schnick, 2005). However, some of these precursors are toxic and harmful to human and environment, and some are unstable and difficult to synthesize on a large scale basis. Therefore, by choosing urea as the starting material had become an alternative (Jinghai Liu, Zhang, Wang, Dawson, & Chen, 2011).

2.8.1 Synthesis of Graphitic Carbon Nitride

Figure 2.10: The formation mechanism of g-C₃N₄ by pyrolysis of urea (Xu, Li, Peng, Lu, & Li, 2013)

Urea being a common, non-toxicity and low cost raw material in chemical industry had turn out to be the promising precursor for synthesizing g-C₃N₄. (J. Liu et al., 2011; Xu et al., 2013). Furthermore, it is an active molecular precursor for thermal treatment. A simple thermal process utilizing it as the starting material in order to synthesis g-C₃N₄ in a large scale had overcome many other synthesis method. First upon heating under a closed air atmosphere, the urea decomposes into ammonia and isocyanic acid. Then it is converted into other intermediates like cyanuric acid, ammelide and ammeline. The formed cyanuric acid further turn into melamine which then condense to form melem. The formation of g-C₃N₄ was formed after the polymerization of melem into melon. The schematic formation mechanism of g-C₃N₄ by pyrolysis of urea is illustrated in Figure 2.10. Liu *et al*, had proven in their studies where they employed a simple pyrolysis of urea under ambient pressure and pyrolysis generated in self-supporting atmosphere produced large scale of g-C₃N₄ (J. Liu et al., 2011). Hence, this simple synthesis processes eliminates the needs of additional additive assistance and higher reaction pressure and atmosphere. The summary of the literature on g-C₃N₄ incorporating with TiO₂ and noble metal is presented in Table 2.4.

The obtained degradation rate on Ag/g-C ₃ N ₄ /RGO was 12.3, 7.2, 5.1 and 3.7 times than that on g-C ₃ N ₄ , Ag/RGO, g-C ₃ N ₄ /RGO and Ag/g-C ₃ N ₄ respectively.	Lu, Shen, Wang, Cui, & Xie, 2015

2.9 Application of Modified Titania Photocatalyst

2.9.1 Photocatalytic Degradation Mechanism of Environment Pollutants

Semiconductor TiO₂ being a well-known photocatalyst for addressing numerous environmental concerns. It was greatly considered by the researchers over the past decades for its improvisation in order to maximize the usage of this notable semiconductor. The primary principles and mechanisms are illustrated in Figure 2.11. When TiO₂ is illuminated with a photon energy (< 390 nm), it will generate and excite an electron from the valence band to the conduction band leaving behind a positively charge hole. This excited electron where it promoted to the conduction band will then undergo oxidation with oxygen molecule to form superoxide anion radicals ([•]O₂⁻) and followed by protonation that yields [•]HO₂ radicals. Then, this radicals combines easily with the trapped electrons to form H₂O₂ and finally to [•]OH an active species radicals. Meanwhile, the

positively charge hole at the valence band is positive enough to generate $\bullet\text{OH}$ radicals at the surface of TiO_2 as shown in the following equations (Khataee & Kasiri, 2010):

The $\bullet\text{OH}$ radical is an active oxidizing agent which is responsible to attack the organic pollutant (OP) present at or near the surface of TiO_2 . It has greater potential to oxidise any form of toxic and bio resistant OP into harmless species such as CO_2 , H_2O and etc. The decomposition can be elucidated through the following reactions (Behnajady & Modirshahla, 2006):

Figure 2.11: General mechanism of photocatalysis on TiO_2 nanomaterials
(Khataee & Kasiri, 2010)

Modifications of titania with different noble metals and conducting carbon materials are required to address all its limitations. Hence, it leads to photocatalytic removal of genera organic pollutants. From the literature survey, it is evident that these modifications resulted in varied photocatalysis mechanism. The studies pertaining to it is reviewed and summarized in Table 2.5.

Table 2.5: Literature studies on photocatalysis mechanism of modified titania

Photocatalyst	Pollutants	Proposed reaction mechanism	Reference
Ag@TiO ₂	Rhodamine B (RhB)	The Ag NPs attach on the surfaces of TiO ₂ forming non-centrosymmetric nano structures due to the different in dielectric environment surrounding the plasmonic Ag. During visible light illumination, the localized surface plasmon resonance effect will then excite electrons to the conduction band of TiO ₂ and leaving behind the holes. The separated electrons and holes then form active radicals.	D. Chen et al., 2013
Ag-TiO ₂	Indigo carmine (IC)	Ag NPs deposited on TiO ₂ surface acted as electron-hole separation center. The electrons are capable to transfer from the TiO ₂ to Ag NPs due to the higher Fermi level of TiO ₂ . This favours the formation of Schottky barrier at the interface. During the light irradiation, (IC) injected electrons to the conduction band of TiO ₂ reacts with O ₂ to form active radicals. Ag NPs acted as the electron traps resulted in prolong the life time of the charge carrier.	Suwanchawalit et al., 2012
Ag/TiO ₂	Methyl Orange and Phenol	During the visible light irradiation, the generated electrons near TiO ₂ surface is mainly due to the resonant surface plasmon induced local electric fields in Ag. They are readily separated from each other and easily migrate to titania. Thus, it suppresses the recombination rate of electron and hole pairs.	Ramchiary & Samdarshi, 2014

Table 2.5, continued

Photocatalyst	Pollutants	Proposed reaction mechanism	Reference
Ag-TiO ₂	Methyl Blue	Under the visible light illumination, electrons in Ag NPs are photoexcited and Ag ⁺ ions are formed due to the LSPR effect. Moreover, the formations of Schottky barrier at the interface due to the larger work function of Ag. The electric field enables the excited electrons to be promoted from the Ag NPs to the TiO ₂ and enhanced the charge separation. Transferred electrons are then react with oxygen to form active radicals. In addition, the Ag ⁺ ions are also reactive radical species. They are able to directly oxidize MB.	Z. Chen et al., 2014
Au/TiO ₂	Acetic acid	Modification of titania with expensive gold had enhanced the separation of charge carriers (e ⁻ /h ⁺). This is attributed to the characteristic of noble metal serving as an electron sink. Hence, more electrons can be participated in the photo degradation of acetic acid and increase the photocatalysis efficiency.	Kowalska, Rau, & Ohtani, 2012
Pd-TiO ₂	Water Splitting	The introduction of Pd onto the TiO ₂ had enable Pd ions to capture the excited electron from titania. Thus, it depresses the recombination rate between the excited electrons and holes. Moreover, the Pd-TiO ₂ has the strong ability of the oxidation - reduction than pure TiO ₂ .	Kwak et al., 2009

Table 2.5, continued

Photocatalyst	Pollutants	Proposed reaction mechanism	Reference
TiO ₂ -RGO	Methylene Blue	After irradiation with visible light, photo excitation in TiO ₂ occurs and generated holes at the valence band. Thus the [•] OH radicals are produced from water, having the potential to degrade the organic pollutants. The photo generated electrons then easily migrate to the surface and react with adsorbed O ₂ in forming [•] O ₂ ⁻ , thereby increasing the overall efficiency.	Umrao et al., 2014
RGO-Ag	Phenol, Bisphenol A and atrazine	Ag NPs acted as the antennae for visible light and RGO acted for efficient electron-hole separation. Visible light excite the Ag surface plasmon and this coherent oscillation generate energetic electrons on its surface. Then, the RGO quickly transports those electrons via its extended π -conjugation structure and lead to suppress the recombination of electron and hole pairs. This electron transfer was feasible due to the work functions of Ag (4.2 eV) and RGO (4.48 eV).	Bhunja & Jana, 2014
Ag-TiO ₂ -RGO	Rhodamine B	Titania with different oxides and consists of many defects give rise to the ability to absorb visible light. It then promotes the electron from the VB to the CB. These electrons then migrate to the Ag NPs and subsequently to RGO. As a result, the electron and holes pairs can be efficiently separated. Eventually, these electrons reduce the dissolved oxygen leading to the formation of [•] O ₂ ⁻ radicals.	Shah et al., 2013

Table 2.5, continued

Photocatalyst	Pollutants	Proposed reaction mechanism	Reference
g-C ₃ N ₄ -TiO ₂	Acid Orange 7	When catalyst is irradiated by UV light, the photogenerated electrons from g-C ₃ N ₄ readily transfer to the CB of TiO ₂ . Where by the holes at the VB of TiO ₂ transfer to VB of g-C ₃ N ₄ . Thus, it suppresses the recombination rate of electron-holes leaving more electrons at the CB of TiO ₂ and more holes in the VB of g-C ₃ N ₄ . In contrast, when it is illuminated by visible light, only g-C ₃ N ₄ is excited because TiO ₂ could not absorb visible light. Therefore the generated electrons in the CB of g-C ₃ N ₄ migrate to CB of TiO ₂ .	Lei et al., 2015
Au/g-C ₃ N ₄	Methyl Orange	Visible light irradiated the catalyst to generate CB electrons and VB holes. These electrons react with oxygen to form superoxide radical anions while the holes react with water to form active [•] OH radicals. The presence of Au NPs acted as the electron traps to prolong the lifetime of the charge carriers. Furthermore, the plasmonic excitation resulted in additional generation of electrical surface charge.	Cheng et al., 2013
g-C ₃ N ₄ /Ag/TiO ₂	Methyl Orange and Phenol	Under the visible light irradiation, only g-C ₃ N ₄ absorbed visible light. The generated electron is then transferred to the CB of TiO ₂ due to more negativity of g-C ₃ N ₄ . Meanwhile, the presence of Ag NPs acted as the electron-conduction bridge where it enhanced the separation of electron and hole pairs. Moreover, with the formation of Schottky barrier it provided an efficient path for the electron to be transferred from g-C ₃ N ₄ toward TiO ₂ . Ag NPs owing to its surface plasmon resonance further enhance the visible light absorption.	N. Chen, Huang, He, Situ & Huang, 2014

Although some works have been carried out in this field, several insights are yet to be explored to fill the gaps of previous research. This includes developing sustainable synthesis method with high quality photocatalyst for enriching their unique inherent characteristics. Demonstrating the visible light photocatalysis ability of the prepared modified synergized photocatalysts in a more appropriate and meaningful way by adopting poor photosensitizing compounds.

CHAPTER 3

METHODOLOGY

This chapter elaborates the comprehensive synthesis methods, characterisations techniques and all the experiments adopted for achieving the adopted objectives.

3.1 Preparation of TiO₂ Template

3.1.1 Materials

Titanium (IV) chloride (TiCl₄, 99.9%) and benzyl alcohol (99.8%, anhydrous) were procured from Sigma Aldrich and tetrahydrofuran (THF) from Fluka. All chemicals were analytical grade and used as received without any further purification.

3.1.2 Synthesis of TiO₂ Template

Synthesis of anatase nanocrystalline TiO₂ in a room temperature by non-hydrolytic polycondensation between titanium (IV) chloride and anhydrous benzyl alcohol was performed in a glass beaker mediated through controlled inert gas (nitrogen) atmosphere. One mL of TiCl₄ was added drop wise into 20 mL of anhydrous benzyl alcohol under vigorous stirring. The reaction is vigorous in nature; the solution initially turns to dark red and then to orange. Further a complete addition of TiCl₄ with continuous stirring yields yellowish solution. The stirring was continued for 24 h and the solution was aged for 21 days at room temperature. The adopted experimental setup up is shown in Figure 3.1. The slow ageing process facilitated through room temperature ensured the formation of more uniform TiO₂ nanoparticles of smaller size

rather than heating at higher temperature. Furthermore aging also dissolved any fluffy white precipitate. The resulting white precipitate after aging was recovered by centrifugation at 3000 rpm for 30 min. The precipitate was thoroughly washed with 20 mL of ethanol and followed by 20 mL of tetrahydrofuran (THF). The washing step was repeated for 3 times and after every washing, the solvent was removed by centrifugation. The practised washing steps ensure the complete removal of excess Cl^- anions. After washing, the obtained TiO_2 white powder was dried at room temperature and the sample is designated as TiO_2 as-synthesized. On the other hand, the as-synthesized sample was calcined at 450°C for 5 h and is designated as calcined TiO_2 . The prepared sample is displayed in Figure 3.2.

Figure 3.1: Experiment setup for synthesis of nanocrystalline anatase TiO_2

Figure 3.2: Photograph of synthesised TiO₂ powders

3.2 Preparation of Plasmonic Photocatalysts Pd/TiO₂ and Ag/TiO₂

3.2.1 Materials

Titanium (IV) chloride (TiCl₄, 99.9%, Merck), Silver Nitrate (AgNO₃, 99.9%, Sigma Aldrich), Sodium tetrachloropalladate (II) (Na₂PdCl₄, 99.998%, Sigma Aldrich), tetrahydrofuran (THF, Fluka), ethylene glycol and benzyl alcohol (99.8% anhydrous, R&M Chemicals) and Milli-Q water (18.2 MΩ·cm). All chemicals were analytical grade and used without any further purification.

3.2.2 Synthesis of Pd/TiO₂ and Ag/TiO₂

The synthesis of pristine anatase TiO₂ was adopted from the above synthesis procedure. The Pd/TiO₂ NPs were synthesized by adding 12 mL of ethylene glycol with

0.4 g of the prepared anatase TiO₂ with a designated amount of Na₂PdCl₄ i.e., 0.5 wt%, 1.0 wt% and 3.0 wt% respectively) for obtaining Pd of similar wt% as stated above. Likewise, the designed amount of AgNO₃ was chosen as Ag precursor for obtaining varied Ag/TiO₂ NPs with varied Ag loading (0.5 wt%, 1.0 wt%, 3.0 wt% and 5.0 wt%). The solution was then exposed under sunlight with continuous stirring for 30 min to promote sustainable photoreduction (~150 and 180 Wm⁻²). The sunlight intensity was measured by using a Lux meter. The obtained precipitate was then centrifuged at 2000 rpm for 5 min. The produced Pd/TiO₂ and Ag/TiO₂ were finally washed with ethanol and deionized water, respectively and followed by overnight drying at 90°C. The amount of Pd and Ag deposited onto TiO₂ is tabulated in Table 3.1.

Table 3.1: The various loading of noble metal Ag and Pd on TiO₂

Weight Percentage (wt %)	Loading amount of Ag (g)	Loading amount of Pd (g)
0.5	0.062	0.062
1.0	0.124	0.124
3.0	0.372	0.372
5.0	0.620	-

3.3 Preparation of Reduced Graphene Oxide and Ag Wrapped TiO₂

3.3.1 Materials

Graphite flakes was purchased from Sigma-Aldrich, potassium permanganate (KMnO₄, 99.9%), sulphuric acid (H₂SO₄, 98%), hydrogen peroxide (H₂O₂, 30%), hydrogen chloride (HCl, 37%) and denatured ethanol (99.7%) were purchased from R&M chemical and Milli-Q water (18.2 MΩ·cm). All chemicals were analytical grade and used as received without any further purification.

3.3.2 Synthesis of Graphene Oxide (GO)

Simplified Hummers method was adopted in synthesis graphite oxide (Hummers Jr & Offeman, 1958). In a typical preparation nature graphite powder (3 g) was oxidized by a mixture of 400 mL of H_2SO_4 and 18 g of KMnO_4 . The mixture was then stirred continuously for three days to ensure complete oxidation of the graphite. Once oxidation process was completed, H_2O_2 solution was added drop wise to terminate the oxidation process. The obtained graphite oxide was constantly washed with 1 M of HCl and Milli-Q water ($18.2 \text{ M}\Omega\cdot\text{cm}$) until it reached pH in between 4–5. This washing process led to the exfoliation of graphite oxide to form GO gel. The solution was then dried overnight at 60°C under vacuum to obtain GO powders and it is depicted in Figure 3.3.

Figure 3.3: Photograph of synthesised GO powders

3.3.3 Synthesis of RGO-Ag/TiO₂

Similar synthesis method for preparation of anatase TiO₂ and Ag/TiO₂ was adopted in preparation of RGO-Ag/TiO₂. 0.2 g of the prepared GO was first dissolved in Milli-Q (18.2 MΩ·cm) water by ultrasonic treatment for an hour to yield a yellow-brown solution. This was followed by the addition of 1 g of the freshly prepared Ag/TiO₂ into the yellow-brown solution and stirred for 1 h until homogeneity was achieved. The solution was then transferred into a Teflon-lined autoclave and was subjected to hydrothermal treatment at 180°C for 6 h. The applied hydrothermal treatment reduced GO to RGO. The resulted suspension was retrieved by centrifugation and washed thoroughly with Milli-Q water (18.2 MΩ·cm) and air dried at room temperature. The schematic of the preparation is illustrated in Figure 3.4.

Figure 3.4: Schematic of synthesis route for RGO-Ag/TiO₂

3.4 Preparation of Graphitic Carbon Nitride and Ag with TiO₂

3.4.1 Materials

Urea and nitric acid were purchased from R&M chemical and Milli-Q water (18.2 MΩ·cm). All chemicals were analytical grade and used as received without any further purification.

3.4.2 Synthesis of g-C₃N₄

A facile thermal heating method was adopted for synthesizing g-C₃N₄. This was achieved by drying the weighted 10 g of urea in an oven at 80°C for 24 h. The dried sample was then pyrolysed at 550°C for 3 h in a Muffle Furnace. The obtained yellow coloured product was then washed with 0.1 M nitric acid and Milli-Q (18.2 MΩ·cm) water for few times in order to remove any residual alkaline species that was absorbed on the sample surface. The washed derivative was finally dried overnight in an oven at 80°C and illustrated in Figure 3.5 (J. Liu et al., 2011).

Figure 3.5: Photograph of synthesised g-C₃N₄ powders

3.4.3 Synthesis of (g-C₃N₄)-Ag/TiO₂

From the prepared g-C₃N₄ sheets a sample weighing 0.012 g was well dispersed in Milli-Q water (18.2 MΩ·cm) ultrasonically. 0.4 g of the as prepared Ag/TiO₂ was then added into the solution and subjected to a reaction at 70°C for 1 h in an open beaker. The resulting suspension was then centrifuged and washed with Milli-Q water (18.2 MΩ·cm) for few times and dried overnight at 60°C. Figure 3.6 depicts the schematic synthesis of (g-C₃N₄)-Ag/TiO₂.

Figure 3.6: Schematic of synthesis route for (g-C₃N₄)-Ag/TiO₂

3.5 Characterization

The morphology of the samples were investigated by field emission scanning electron microscope (FESEM, Hitachi SU-8000) equipped with an energy dispersive X-ray spectroscopy (EDS, Zeiss Auriga). The images were recorded at an accelerating voltage of 20 kV. Transmission electron microscope (TEM) (Philips CM-12) and high resolution transmission electron microscope (HRTEM, JEM-2100F, Jeol) images were obtained at 200 kV. The phase composition were analysed by X-ray diffraction (XRD, Bruker D8 advance X-ray powder diffractometer with Cu K α radiation $\lambda=0.154$ nm). A micro-PL/Raman spectroscopy with the excitation wavelength at 514 nm and 325 nm (Renishaw, inVia Raman Microscope) was used to acquire the Raman and photoluminescence (PL) spectra. A Fourier transform infrared (FTIR) spectrum was obtained by Perkin Elmer Spectrum 400 spectrophotometer with scan range of 4000 – 450 cm⁻¹. Brunauer-Emmett-Teller (BET) surface area, pore volume, and Barret-Joyner-Halenda (BJH) pore size distribution based on nitrogen adsorption-desorption isotherms with TriStar II 3020 (Micrometrics®, USA). Prior to the analysis, the samples were degassed at 150°C for 5 h under nitrogen atmosphere. X-ray photoelectron spectra (XPS) were obtained with Axis Ultra DLD instrument of Kratos using monochromatic AlK α radiation (225 W, 15 mA, 15 kV). The C1s binding energy of adventitious carbon (284.9 eV) was used as reference. UV-Vis diffuse reflectance spectra (UV-DRS) were performed through Shimadzu UV-2600 spectrophotometer equipped with an integrating sphere attachment. The spectra were obtained with BaSO₄ as a reference.

3.6 Photocatalysis Experiments

3.6.1 Solar Photocatalysis

The solar photocatalytic performance of the prepared TiO₂ was evaluated by adopting a recalcitrant, non-photosensitising pesticide 2, 4-dichlorophenol (2, 4-DCP) as model pollutant. The experiments were carried out in a batch reactor of 500 mL capacity with a working volume of 250 mL (initial concentration of 2, 4-DCP = 50 mg/L) under stirring condition. The solar light was employed as the source of irradiation with the presence of 1 g of synthesized photocatalyst. The sunlight intensity during the experiments was fluctuated between 88 and 205 Wm⁻². A dark experiments were carried out prior to photocatalytic experiments to substantiate the possibility of parallel removal of contaminant molecule (2, 4-DCP) by adsorption and non-degradation of pollutant in the absence of light source. Additional control experiments were carried out with zero photocatalyst condition to ensure the degradation was only due to presence of photocatalyst. The samples were drawn out at regular intervals (30 min) and analysed for residual concentration of 2, 4-DCP using an ultra-performance liquid chromatography (Acquity UPLC H-Class, Waters). The parameters are tabulated in Table 3.2.

Table 3.2: LC analysis conditions for 2, 4-DCP

Pollutant	2, 4-DCP
Column	C18 (2.1 × 50 mm, 1.7 µm)
Mobile phase	Acetonitrile : Water (60:40)
Flow rate (mL/min)	0.4
Wavelength (nm)	285

The adopted calibration curve is illustrated in Figure 3.7. The degree of mineralization of 2, 4-DCP during photocatalytic experiment was estimated by Total Organic Carbon (TOC) analysis using O. I Analytical Aurora 1030W TOC Analyzer. Figure 3.8 shows the schematic experimental setup for solar photocatalysis of 2, 4-DCP.

Figure 3.7: Calibration curve for 2, 4-DCP

Figure 3.8: Experimental setup for solar photocatalysis experiment

3.6.2 Artificial Visible Light Photocatalysis

The photocatalytic performance of the prepared Ag/TiO_2 was evaluated by degrading two different types of pollutants namely, 2, 4-dichlorophenol (2, 4-DCP) and Amoxicillin (AMX). Then, Bisphenol A (BPA), Methylene Blue (MB) and Reactive Blue 19 (RB19) were chosen as pollutants to measure the photodegradation efficiency of (RGO-Ag/TiO_2) . Meanwhile, the photocatalysis degradation efficiency of Pd/TiO_2 and $(\text{g-C}_3\text{N}_4)\text{-Ag/TiO}_2$ were studied by adopting AMX as pollutant. The pollutants 2, 4-DCP, AMX and BPA are classified as Endocrine Disrupting Compounds (EDCs) with poor photosensitising ability. All the experiments were performed as batch process with a simple 500 mL borosilicate beaker with a working volume of 250 mL. The initial concentrations of all pollutants in these studies were set at 20 mg/L with 1 g

photocatalyst loading under stirring conditions. The artificial photons were generated by 500 W tungsten-halogen lamps with high-pass UV filter (FSQ-GG400, Newport Corp). All experiments were performed under identical condition for a specific period of time. Respective control experiments were carried out with zero photocatalyst condition to ensure the photocatalytic degradation. The samples were drawn out at regular intervals, analysed for residual concentration of the pollutants using Acquity UPLC H-Class, Waters. The analysis parameters are tabulated in Table 3.3.

Table 3.3: LC analysis conditions for studied pollutants

Pollutant	Amoxicillin	Bisphenol A
Column	C18 (2.1 × 50 mm, 1.7 µm)	
Mobile phase	KH ₂ PO ₄ (pH1.8) : Methanol (80:20)	Water : ACN (60:40)
Flow rate (mL/min)	0.4	
Column Temperature (°C)	40	
Sample Temperature (°C)	Room Temperature	10
Wavelength (nm)	228	226

The dyes MB and RB19 concentration was analysed by using visible spectrometer (Spectroquant® Pharo 100, Merck) at λ_{max} = 664 nm and 596 nm respectively. The degree of mineralization of all pollutants was expressed as TOC using O.I Analytical Aurora 1030W TOC Analyzer. Figure 3.9-3.12 portrait the calibration curve for AMX, BPA, MB and RB19 respectively. The schematic of the experimental setup is displayed in Figure 3.13.

CHAPTER 4

RESULTS AND DISCUSSION

This chapter presents the obtained results along with the analysis, inferences and science behind those observations. The preliminary section of the chapter discusses on the characteristics of the synthesized template TiO₂. The later sections present the evolution of synergised Titania achieved with the support of noble metals, conducting carbon material through sustainable approach for enhancement of visible light photocatalysis.

4.1 Anatase Template TiO₂

The present work is aimed to investigate the photocatalytic activity of anatase template TiO₂ synthesized through modified non-hydrolytic route using TiCl₄ as a precursor. The technique delivered two samples of varied characteristics and are designated as-synthesized and calcined. Thus obtained were characterized with various analytical characterization techniques for understanding the materials chemistry. Furthermore, their photocatalytic performance was evaluated by degrading 2, 4-DCP under solar light irradiation.

Figure 4.1 depicts the XRD patterns of the titania nanoparticles. The obtained diffraction peaks were synchronised well with the JCPDS card No: 21-1272 indicating the body-centered tetragonal anatase phase of TiO₂. The diffraction peaks at $2\theta = 25.25^\circ$ (101), 47.98° (200), 53.59° (105), 37.82° (004) and 62.36° (215) were all corresponds to the lattice plane of complete anatase phase. The peaks at $2\theta = 27.5^\circ$ (110) and 30.8° (121)

signifies the absence of rutile and brookite and further confirms both the synthesized TiO_2 bear complete anatase phase. The as-synthesized one showed a wide peak (25.25°) with more background disturbances indicating the amorphous nature. A sharp and more intense peak (Figure 4.1 (b)) was obtained for the calcined and was attributed to improved crystallinity and crystallite size achieved through heat treatment (W. Li & Zeng, 2011). Crystallite grain sizes were calculated using Scherer's formula.

$$D = \frac{k\lambda}{\beta \cos\theta} \quad (4.1)$$

where, D is the crystallite size (nm), k is the shape constant (0.9), λ is the wave length of $\text{CuK}\alpha$ radiation (0.154 nm), θ is the diffraction angle (degree) and β is the full width at half maximum. The crystallite sizes were calculated to be 4.65 and 14.8 nm for as-synthesized and calcined samples respectively.

Figure 4.1: XRD diffraction pattern of (a) as-synthesized TiO_2 (b) calcined TiO_2

The Raman spectra of the prepared samples are presented in Figure 4.2. Two notable broad bands at 425 and 609 cm^{-1} was observed for the as-synthesized TiO_2 confirming the presence of amorphous phase. On the other hand calcined exhibited two minor bands at 399, 515 and a prominent band at 639 cm^{-1} correspond to the unique characteristic of crystalline anatase TiO_2 . The obtained Raman shift after calcination well clarified the increase in the crystallinity and crystallite size. While the non-occurrence of bands at 445 and 612 cm^{-1} indicates the complete absence of rutile phases. Thus Raman spectrum of samples also confirms the presence of complete anatase phase (W. Li & Zeng, 2011; Tompsett et al., 1995; T. Zeng, Qiu, Chen, & Song, 1998).

Figure 4.2: Raman Spectra of titania nanoparticles (a) as-synthesized TiO_2 (b) calcined TiO_2

The morphological images of the achieved anatase titania nanoparticles were depicted in Figure 4.3 (a-f). Figure 4.3 (a-c) signifies the amorphous nature of as-synthesized TiO_2 with a clear observation of uniform spherical shape and agglomeration. Where else Figure 4.3 (d-e) denotes the spheroid shaped with uniform size particles distributed homogeneously for the calcined. Higher magnification images clearly illustrate the amorphous nature of as-synthesized (Figure 4.3 (c)) and crystalline nature of calcined sample (Figure 4.3 (f)). The obtained images showed a higher particle size due to agglomeration of the nanoparticles. Further the images also revealed the more uniformity nature for the as-synthesised over calcined.

Figure 4.3: FESEM images of (a-c) as-synthesized TiO₂ (d-f) calcined TiO₂

The particle size of the titania was measured using TEM and presented in Figure 4.4 (a) and (b). The diameter of the as-synthesized TiO₂ was ranged between 3 and 6 nm (Figure 4.4 (a)). Similarly the diameter of the calcined TiO₂ was between 11 and 15 nm. The increase in particle size was attributed to the temperature effect and the obtained results were very well correlated with the crystallite size measured by XRD analysis. Although there is a morphological variation of the as-synthesized and calcined TiO₂ but the particles were more uniform in nature. The EDX spectra of the anatase TiO₂ were analyzed and the spectra showed the presence of Ti and O elements (Figure 4.5). The absence of the Cl⁻ ion confirms the effectiveness of the adopted washing procedure was in removing the unwanted anion (Cl⁻).

Figure 4.4: TEM images of (a) as-synthesized TiO₂ (b) calcined TiO₂

Figure 4.5: EDX spectra of anatase TiO₂

Nitrogen adsorption-desorption isotherms and corresponding pore size distribution of both as-synthesized and calcined TiO₂ was depicted in Figure 4.6 (a) and (b). Both the samples revealed a stepwise adsorption-desorption represented by type IV isotherms according to the IUPAC classification. The hysteresis loops indicates the slit-shaped pores for as-synthesized TiO₂ and cylindrical shaped pores for calcined TiO₂. The BET surface area of the as-synthesized and calcined TiO₂ was found to be 147.34 and 64.92 m²/g, respectively. A sharp decrease in the BET surface area of the calcined TiO₂ was ascribed to the gradual increase in grain size during calcination. In addition, the average pore diameter, determined by Barrett–Joyner–Halenda (BJH) method (inset of Figure 4.6 (a) and (b)) increased after calcination. The pore size distribution indicates that the as-synthesized TiO₂ had a smaller pore size (3.46 nm) than calcined TiO₂ (9.24 nm). Bimodal pore size distributions observed for calcined TiO₂ and were attributed to the uncontrollable pore collapse during calcination and also reflect the detrimental effect in photocatalytic performance. It is known that the mesoporous anatase TiO₂ possessing both high surface area and crystallinity bear good photocatalytic properties (Q. Zhang et al., 2011). Although the surface area of the calcined TiO₂ was low compared to as-synthesized, the increased crystallinity of calcined showed a salutary effect in

photocatalytic activity. In addition, solar energy conversion efficiency may vary based on the particle size and pore size distribution (Parmar, Ramasamy, Lee, & Lee, 2010). At times, very small average pore size of anatase TiO₂ would hinder the access of organic pollutants resulting in poor degradation. Hence both the anatase TiO₂ nanoparticles were experimented for their photocatalytic activity under sunlight irradiation.

High resolution XPS spectra of both the anatase nanoparticles were shown in Figure 4.7 (a) and (b). Both the TiO₂ nanoparticles exhibited similar pattern with existence of Ti 2p shell element. In general, the Ti 2p peak is varied between 456 and 464 eV. The obtained broad peak at 463 eV and a sharp narrow peak at around 458 eV for both the as-synthesized and calcined indicate the presence of Ti and Ti⁴⁺ species. These peaks are attributed to an active site which improves the photocatalytic activity, especially under the solar light irradiation (Aziz, Puma, Ibrahim, & Saravanan, 2013).

Figure 4.6: Adsorption-desorption isotherm of (a) as-synthesized TiO_2 (b) calcined TiO_2 along with the pore size distribution

Figure 4.7: XPS spectra of Ti (a) as-synthesized TiO₂ (b) calcined TiO₂

The UV-Vis absorption spectra of the anatase TiO₂ samples were shown in Figure 4.8. The obtained spectrum depicts the response of the prepared TiO₂ in both UV and visible light spectrum. From the spectrum an evident strong increase in absorption at 425 nm was observed and is attributed to the excitations of electrons from the valence band to the conduction band of titania. Kulbeka-Munk equation was used to obtain the band gap energy of TiO₂ nanoparticles. The reflectance data was translated to the absorption coefficient $F(R_{\infty})$ values and is shown in Figure 4.9 (Burgeth & Kisch, 2002; Lin et al., 2006; Valencia, Marín, & Restrepo, 2010):

$$F(R_{\infty}) = \frac{(1 - R_{\infty})^2}{2R_{\infty}} \quad (4.2)$$

where, R_{∞} is the diffused reflectance of at the given wavelength

$$E(\text{eV}) = \frac{hC}{\lambda} \quad (4.3)$$

where, h is the Planck's constant (6.626×10^{-34} Js), C is the speed of light (3.0×10^8 ms⁻¹) and λ is the wavelength (nm). From the Kulbeka-Munk analysis, the band gap energy of the as-synthesized and calcined TiO₂ was found to be 3.1 and 3.25 eV respectively. The increase in band gap energy for calcined TiO₂ was signified to the increase in crystallinity of calcined than the as-synthesized.

Figure 4.8: UV-Vis absorption spectra of prepared TiO₂ photocatalysts

Figure 4.9: Calculated band gap energy of prepared TiO₂ photocatalysts

The results of control experiments and photocatalytic degradation experiments of 50 mg/L (250 ml solution) of 2, 4-DCP on as-synthesized and calcined TiO₂ under the solar light irradiation were depicted in Figure 4.10. The obtained results suggests that a complete degradation of 2, 4-DCP was achieved using both the TiO₂ photocatalysts with variation in time duration. The control experiments confirms that only a limited amount of 2, 4-DCP was removed (<1%) in the absence of the TiO₂ photocatalysts by direct photolysis. From the dark reactions (Figure 4.10), it was clear that a modest removal of 2, 4-DCP was occurred due to adsorption (10-12% for as-synthesized TiO₂ and 18-20% for calcined TiO₂). Almost complete degradation (99-100%) was achieved for both the samples under solar light radiation; however, the as-synthesized TiO₂ took longer period of 3.5 h than calcined that took 2.5 h. According to the optical spectra and band gap energy value the as-synthesized TiO₂ was expected to possess better photocatalytic

activity than the calcined TiO_2 . However, the obtained upturned observance was attributed due to various reasons. The photocatalytic activity depends on the efficiency of utilization of the fraction of incident light absorbed by the catalyst (Ahn, Kim, Kim, & Hahn, 2003; Dolat, Quici, Kusiak-Nejman, Morawski, & Li Puma, 2012; Pupo Nogueira & Guimarães, 2000; Sérgio, Melo Jorge, Maneira, & Nunes, 2011). In an irradiated suspension of photocatalyst particles photons were absorbed and scattered. Owing to amorphous nature of the as-synthesized photocatalyst the scattering of incident solar light energy was more than the absorbed energy (results in decreased formation of electron and hole pairs) as compared to that of calcined, and resulted in deprived photocatalytic activity. In addition amorphous surface has many defects that act as an active recombination centers for the photo generated electrons and holes, which further decreased the photocatalytic activity. Furthermore, when particle size become extremely small (i.e. ≤ 5 nm in diameter), most of the generated electron and hole pairs may quickly reach the surface and undergo a rapid surface recombination that reduces the photocatalytic activity of the as-synthesized one (Hines & Guyot-Sionnest, 1996; N Serpone, Lawless, Khairutdinov, & Pelizzetti, 1995). The other possibility for deprived photocatalytic activity of as-synthesized might be due to overloading of the photocatalyst (excess of photocatalyst particles scatters the sunlight) and also due to agglomeration of particles that hinders the penetration of sunlight.

From the dark reactions, it is clear that the adsorption capacity of 2, 4-DCP is higher for calcined than as-synthesized. Although the as-synthesized has higher surface area than the calcined, the high adsorption capacity was attributed to the surface charge characteristics. The calcination step contributed for the increment of crystallinity and the surface charge and led to increased adsorption of 2, 4-DCP. Thus in the calcined sample the photogenerated electrons were readily trapped on Ti^{4+} sites and form Ti^{3+} that traps the electrons and readily scavenged by oxygen. Hence, the localized holes can be

scavenged by either reacting with hydroxide ions or through electron transfer with water to form hydroxyl and super oxide radicals (Almquist & Biswas, 2002; Ilisz, Dombi, Mogyorósi, Farkas, & Dékány, 2002; Li Puma & Yue, 2002; Lin et al., 2006). In the case of as-synthesized a similar number or more electrons and hole pairs were generated. However smaller particle size and higher surface area favored the recombination of the generated electron and hole pair resulting a deprived photocatalytic activity over calcined. Thus the photocatalytic activity of as-synthesized declined in spite of lower band gap energy (3.1 eV). Photocatalytic degradation potential of the as-synthesized and calcined TiO₂ was compared with different phenolic compounds under various irradiation sources and listed in Table 4.1. It was clear from the Table 4.1, that the UV as a source of irradiation resulted in better photocatalytic performance than visible light irradiation attributed to the band gap energy of the TiO₂ photocatalysts that can utilize only the wavelength less than 380 nm. It was also evident from the Table 4.1 that the synthesized photocatalysts has the potential to utilize the solar energy emerged with higher photocatalytic activity to completely degrade the 2, 4-DCP in a reasonable time.

Figure 4.10: Photocatalytic evaluation of 2, 4-DCP by prepared TiO₂ photocatalysts under solar irradiation

The degree of mineralization of 2, 4-DCP during the photocatalysis was analysed as a function of TOC and depicted in Figure 4.11. An efficiency of 73.5% was achieved for as-synthesized TiO₂ while 61.5% for calcined one, respectively. A higher degree of mineralization was achieved for as-synthesized (73.5%) compared to that of calcined TiO₂ (61.5%) was again attributed to its smaller crystallite size and larger surface area. Only a significant mineralization occurred during dark experiment (< 9.0%) and control experiment (<1.0%) confirms that the mineralization was due to photocatalysis.

Figure 4.11: Percentage mineralization of 2, 4-DCP based on TOC analysis

The degradation kinetics of 2, 4-DCP on as-synthesized and calcined TiO₂ heterogeneous catalysts is explained by the first-order kinetics (K. V. Kumar, Porkodi, & Rocha, 2008). The first-order expression is given below.

$$-\ln \frac{C}{C_0} = k_1 t \quad (4.4)$$

where, C_0 is the initial concentration of 2, 4-DCP (mg/L) and C is the concentration 2, 4-DCP at time t and k_1 represents the rate constant of first order reaction (min^{-1}). The obtained experimental data were fitted with first order kinetics and presented in Figure 4.12. Higher correlation coefficients ($r^2 > 0.97$) obtained for both the TiO₂ photocatalysts indicates that the degradation of 2, 4-DCP followed first-order kinetics. The first order reaction rate constants (k_1) were found to be 0.017 and 0.028 min^{-1} for as-synthesized and

calcined TiO_2 , respectively. Higher rate constant value of calcined TiO_2 indicates its potential for higher photocatalytic activity over as-synthesized.

Figure 4.12: The kinetics of 2, 4-DCP degradation

Though an appreciable achievement was exhibited by the template TiO_2 , but it still trail as an active visible light photocatalyst. Hence the necessary modifications were adopted for its successfulness as a visible light photocatalyst.

4.2 Palladium Modified TiO₂ for Synergised Visible Light Activity

The modification was approached by adopting a facile, ease and sustainable method with the support of noble metal (Pd) onto TiO₂. The Palladium NPs was chosen as a potential supporting candidate due to its high reactivity towards photocatalytic activity and reluctant toward surface oxidation. To the best of our knowledge, this is the first report on utilizing sustainable approach for the deposition of the Pd NPs onto TiO₂.

4.2.1 Deposition of Pd onto TiO₂ through Sustainable Route

The Pd/TiO₂ nanoparticles were synthesized via photodeposition with the aid of solar energy. The energy obtained from the exposed solar energy was adequate for the reduction and deposition of palladium onto TiO₂ surface. This was achieved by exciting TiO₂ under natural sunlight for the formation of electrons and holes. The generated electrons being excited to the conduction band (CB) which served as an electron source for reduction of palladium cations. The photoelectrons generated by TiO₂ reduced the Pd²⁺ to palladium nanoparticle and the holes from the valence band (VB) react with ethylene glycol to form aldehyde. The complete mechanism is illustrated in Figure 4.13.

Figure 4.13: Schematic diagram for synthesis of Pd/TiO₂ via solar assisted photodeposition

4.2.2 Characterization

The synthesized modified photocatalyst was thoroughly investigated for its intrinsic nature. Figure 4.14 (a-c) depicts the morphological images of Pd/TiO₂ photocatalyst. It is evident from the obtained images that the synthesized palladium NPs is uniformly deposited onto the surface of TiO₂. It could be clearly seen from the Figure 4.14 (b) and (c) that TiO₂ particles are in spheroid shape with homogenous distribution. Where else, the Pd NPs exhibited spherical morphology with particles size ranging from 17-29 nm. The inset in Figure 4.14 (c) shows the corresponding EDX spectrum, confirming the presence elements in the synthesized photocatalysts. The HRTEM images (Figure 4.14 (d) and (e)) further confirmed the better formation of Pd/TiO₂ without changing the original morphology of TiO₂. It also further confirms the particles size of palladium. The presence of lattice fringes 0.22 nm and 0.35 nm spacing as seen in Figure 4.14 (f) clearly attributed to the face centered cubic (FCC) Pd (1 1 1) and anatase TiO₂ (1 0 1) planes, respectively (X. Chen et al., 2011; Mohapatra et al., 2008; Pan & Xu, 2013a; Xiong, Chen, et al., 2005). This also signifies the heterojunction formation between Pd and TiO₂, a mean for visible light absorption.

Figure 4.14: FESEM images of the (a) low magnification, (b-c) high magnification of 0.5wt% Pd/TiO₂. The inset of (c) is the EDX of 0.5wt% Pd/TiO₂ and (d-f) HRTEM images of 0.5wt% Pd/TiO₂

Figure 4.15 shows the X-ray diffraction patterns of anatase TiO₂ and Pd/TiO₂ with different Pd loading (0.5wt%, 1.0wt% and 3.0wt %). Pure anatase TiO₂ is observed in all samples indicating that its crystallinity and the phase is not distorted by the solar assisted photodeposition. The diffraction patterns of the prepared anatase TiO₂ well correlated with the standard peaks (JCPDS no. 21-1272). The presence of Pd NPs are signified by a diffraction peaks appeared at $2\theta = 40.1^\circ$ and 46.7° . They are assigned to (1 1 1) and (2 0 0) crystal plane of face centered cubic (FCC) Pd (JCPDS no 46-1043) respectively. From the diffraction patterns only two peaks instead of three that designates Pd was observed. This was due to the peak overlap with the anatase TiO₂ at $2\theta = 68.1^\circ$ (2 2 0) and pretends to be two peaks. Thus these three diffraction peaks further signifies the metallic state of the loaded Pd NPs. The peaks also confirm the stability of the synthesized palladium crystals that has a notable contribution to promising visible light performance (Chan, Chang, Hsu, Wang, & Lin, 2009). Overall, the prepared samples showed higher crystallinity that is ascertained by the sharp peaks. The average crystalline sizes of anatase TiO₂ and Pd particles were calculated using well know Scherrer equation. The crystalline size of the Pd particles was found to be 21.22 nm, 22.41 nm and 28.10 nm for 0.5wt% Pd/TiO₂, 1.0wt% Pd/TiO₂ and 3.0wt% Pd/TiO₂ respectively. No significant changes in crystalline size of anatase TiO₂ (19.75 nm) was observed after depositing Pd (19.57 nm). This very well clarified that Pd was deposited onto the TiO₂ surface and not incorporated into the TiO₂ lattice.

Figure 4.15: X-ray diffraction patterns of (a) TiO₂, (b) 0.5wt% Pd/TiO₂, (c) 1.0wt% Pd/TiO₂ and (d) 3.0wt% Pd/TiO₂

The Raman spectrum of the synthesized samples was shown in Figure 4.16. As usual four distinct peaks were detected at 145 (E_g), 399 (B_{1g}), 519 (A_{1g} + B_{1g}) and 639 cm⁻¹ (E_g) that attributes to the pristine anatase phase of the synthesized TiO₂. It was evident that the deposition never distorted the phase of the TiO₂. These well matched with XRD analysis where the prepared samples are purely in crystalline anatase with the absence of rutile phase bands at 445 and 612 cm⁻¹ (W. Li & Zeng, 2011).

Figure 4.16: Raman spectra of (a) TiO₂, (b) 0.5wt% Pd/TiO₂, (c) 1.0wt% Pd/TiO₂ and (d) 3.0wt% Pd/TiO₂

The specific surface area and pore characteristics of the prepared samples are depicted in Figure 4.17 (a-d). All the samples demonstrated a stepwise adsorption - desorption hysteresis, well explained by type IV isotherms according to IUPAC classification with mesoporous characteristics (Pan & Xu, 2013b). The obtained BET surface area, average pore size and pore volume after Pd deposition is summarized in Table 4.2. In addition, the average pore diameter, determined by BJH method using the desorption isotherm was found to decrease after the deposition of Pd NPs (inset of Figure 4.17). The trivial decrease in BET surface area and average pore diameter was due to minor blockage of pores in anatase TiO₂ by the deposited Pd NPs (Pan & Xu, 2013a).

Figure 4.17: Adsorption-desorption isotherm of (a) TiO₂, (b) 0.5wt% Pd/TiO₂, (c) 1.0wt% Pd/TiO₂ and (d) 3.0wt% Pd/TiO₂ and the inset is the pore size distribution

Table 4.2: The surface characteristics of modified TiO₂ with varied Pd loading

Sample	BET surface area (m ² /g)	Average pore size (nm)	Pore volume (cm ³ /g)
Anatase TiO ₂	52.2374	12.9256	0.2098
0.5wt% Pd/TiO ₂	46.6761	14.3101	0.2031
1.0wt% Pd/TiO ₂	48.7703	12.9295	0.1949
3.0wt% Pd/TiO ₂	48.6139	13.0052	0.1978

In order to determine the chemical composition and oxidation state for the prepared photocatalyst was subjected to X-ray photoelectron spectroscopy and the obtained spectrum are presented in Figure 4.18 (a). From the figure two peaks were observed at binding energies of 458.8 eV and 464.4 eV which corresponded to Ti 2p_{3/2} and Ti 2p_{1/2} spin-orbital splitting photoelectrons for anatase TiO₂ respectively (Kwak et al., 2009). These indicate the presence of typical Ti⁴⁺ in the synthesized samples. The presence of Pd NPs can be distinguished by two peaks centered at binding energies of 334.3 eV and 340.0 eV which is assigned to Pd 3d_{5/2} and Pd 3d_{3/2} respectively (Figure 4.18b) (Pan & Xu, 2013a). Thus confirming the predominant metallic form existence of the deposited noble metal.

Figure 4.18: Core level XPS spectra of (a) Ti 2p and (b) Pd 3d of 0.5wt% Pd/TiO₂

The obtained optical absorbance spectrum is shown in Figure 4.19. The anatase TiO_2 showed almost zero absorption (~ 0.1 a.u) in the visible region. However, the deposition of Pd NPs caused a significant shift towards the visible region because of the surface plasmon absorption of palladium particles. The Pd particles < 10 nm are capable to absorb the UV region, however particles > 10 nm exhibits a red shift and enhances visible light absorption ability (Mohapatra et al., 2008; Xiong, Chen, et al., 2005). This ascends from the different polarization field induced through the surface charges affected by the amplitude and relative phase of the scattered and incident fields (Murray & Barnes, 2007). Thus it is well correlated with our present findings, where the average particles size of palladium was in the range of (17–29 nm). Therefore, with the broad absorption peak between 450-500 nm observed on Pd/ TiO_2 with different palladium deposition, clearly showed the contribution of metallic Pd NPs. Although a small amount of Pd NPs enhanced the visible light absorption further surge in the Pd loading contributed for its excess presence. This induced dominant light scattering phenomena resulted in deprived performance (Kwak et al., 2009; W. Wang, Cheng, Yu, Liu, & Fan, 2012).

Figure 4.19: UV-visible absorption spectra of (a) TiO_2 , (b) 3.0wt% Pd/ TiO_2 , (c) 0.5wt% Pd/ TiO_2 and (d) 1.0wt% Pd/ TiO_2

PL spectra are often employed to understand the surface processes involving the photogenerated electron-hole pairs (N. Zhang, Liu, Fu, & Xu, 2011). The obtained PL spectrum in Figure 4.20 shows the emission intensity that relates with the recombination rate of the excited electron and hole pairs. Lower PL intensity indicates that a lower recombination rate of electrons and holes due to more excited electrons are either transferred or trapped. The emission peak of Pd/ TiO_2 is obviously quenched as compared to that of TiO_2 . This further revealed that the deposition of Pd NPs has enhanced the trapping or transferring of electron and there by suppressing the electron-hole recombination. This high charge carrier separation efficiency extends the reactive electron-hole lifetime and hence leads to a better photocatalytic performance.

Figure 4.20: Photoluminescence spectra of (a) TiO_2 , (b) 0.5wt% Pd/TiO_2 , (c) 3.0wt% Pd/TiO_2 and (d) 1.0wt% Pd/TiO_2

Figure 4.21 shows the photocatalysis performance of the prepared samples (Pd/TiO_2) for the degradation of AMX under artificial visible light irradiation. The obtained results showed an excellent efficiency achieved irrespective of palladium loading with an initial AMX concentration of 20 mg/L. The degradation followed an order of 97.5% (0.5wt% Pd/TiO_2) > 83.4% (3.0wt% Pd/TiO_2) > 78.7% (1.0wt% Pd/TiO_2) > 27.5% (TiO_2) respectively. The control experiment with the absence of photocatalysts showed almost nil degradation and proved the poor photosensitizing ability of AMX. A significant enhancement in the degradation efficiency was achieved by depositing Pd NPs as compared to pure. This immense progress was attributed to the localized surface plasmon resonance and triggered Pd NPs to absorb visible light. This was further attributed to an optical excitation that produced a coherent oscillation of free electrons in the resonance with the electrical field component of incoming electromagnetic irradiation

(Kochuveedu et al., 2013; Lang et al., 2014; Qu & Duan, 2013). During the incidence of photons onto noble Pd NPs, the electron density of the metal was then polarized to one side and further oscillates within the resonance of light frequency (Bumajdad & Madkour, 2014). The absorption of visible light by Pd NPs is also a functionality of particle size and smaller Pd particles (<10 nm) are well received by the UV irradiation, where else the larger particles by visible light (Mohapatra et al., 2008; Xiong, Chen, et al., 2005; Xiong, Wiley, et al., 2005). The findings were observed in the present study where by a notable degradation was achieved for the Pd with particle size 17–29 nm. However, pure anatase TiO₂ showed a very poor degradation of AMX. This was attributed to its own characteristic of having large band gap energy which hinder the absorption in the visible region as shown in our optical absorbance spectrum. Therefore with the low absorption of energy, only minimum electrons can be excited from the VB to CB of TiO₂ and thus led to such inference.

Figure 4.21: Photocatalytic degradation rates of AMX under artificial visible light irradiation

The degradation mechanism and electron transfer was explained in Figure 4.22. When Pd/TiO₂ is exposed to the visible light, the plasmon resonance excites the electrons below the Fermi level of the Pd NPs in the VB to be transferred to CB leaving behind the positive charges (h⁺) at VB. Since the CB of TiO₂ is an electron acceptors, it readily accepts the electrons that are transferred from Pd NPs to form superoxide anion radicals (•O₂⁻). This was followed by protonation reaction that results in •HO₂ radicals. Thus formed instable •HO₂ radicals further combines with trapped electron to form H₂O₂, and lead to the formation of hydroxyl radicals (•OH). They are the active species that are responsible for the degradation. Besides that, when Pd NPs interacts with TiO₂ Schottky junction is promoted and build an internal electric field close to the interface (Kochuveedu et al., 2013; Zhou et al., 2012). Thus it drives the generated electrons and holes to move in different directions and the photon energies of electrons excited upon LSPR are able to cross the energy junction at the interface. As a result electrons are transferred from Pd NPs to CB of TiO₂ (Lang et al., 2014; Linic et al., 2011). Furthermore with the formation of Schottky junction, it shrinks the recombination of electrons and holes, and prolongs the lifetime of the charge carriers (X. Zhang et al., 2013). Therefore with the complement of this mechanism supported by Pd NPs showed an exemplary photocatalytic performance in shorter duration.

Figure 4.22: Schematic diagram of electron transfer and degradation mechanism of AMX

Meanwhile, in the study on influence of palladium weight percentage (0.5wt%, 1.0wt% and 3.0wt %) on the photocatalytic efficiency, it showed an optimum value at 0.5wt%. According to the optical spectra and photoluminescence analysis the 1.0wt% Pd/TiO₂ was expected to yield better photocatalytic efficiency as compare to the rest. However, the obtained contradictory observance was attributed to the following reasons. During the irradiation of suspension of photocatalyst particles, photon are absorbed and scattered. As observed in the optical spectra similar peak broadening phenomenon was observed for 1.0wt% owing to the scattering of light. Thus it destruct the absorption of visible light due to the shielding effect exhibited by the Pd layers and resulting in low generation of active electrons (Kwak et al., 2009; W. Wang et al., 2012). Therefore, it results in lower photocatalytic degradation efficiency as compare to others though it has the lowest recombination of electron and hole pairs.

Stability of the prepared photocatalyst is significantly important for real time applications. Therefore it was carried out through recycle experiment under identical conditions and shown Figure 4.23. The photocatalytic activity of 0.5wt% Pd/TiO₂ exhibited 92.3% and was able to achieve even after the 3rd run, there by establishing the excellent photostability. The kinetics of the photocatalytic degradation of AMX best fitted to the pseudo first-order reaction kinetics (Figure 4.24). The obtained kinetics parameters are tabulated in Table 4.3. Finally the degree of mineralization of AMX during the photocatalytic degradation was also presented through a TOC analysis and depicted in Figure 4.25. The TOC results well corresponds with the degradation trend analysed through UPLC. Over all the study showed that the adopted Pd noble metal played a key role in enhancing the visible light harvesting and prolonged the life time of charge carriers.

However the study motivated us to expand the search with other noble metal. Hence Ag a well-known noble metal was chosen as a potential visible light enhancer. The Ag was tailored with the TiO₂ through a similar sustainable photodeposition and the

obtained inherent materials and photocatalytic characteristics are discussed in the following section.

4.3 Silver Modified TiO₂ for Synergised Visible Light Activity

Figure 4.26 depicts the X-ray diffraction pattern of Ag/TiO₂ with varied Ag loading (0.5wt%, 1.0wt%, 3.0wt% and 5.0wt %) along with pure TiO₂. The anatase phase of the titania and well supported with the JCPDS no 21-1272. The sustainable synthesis of Ag NPs assisted through sun light exhibited diffraction peaks at $2\theta = 38.1^\circ$ (1 1 1), 44.3° (2 0 0), 64.4° (2 2 0) and 77.4° (3 1 1) planes with face centered cubic (FCC) attributed to Ag (JCPDS no 04-0783) with increase in Ag diffraction peaks for increased in Ag loading. However, 0.5wt% loading does not show any peak due to its lower concentration (i.e. below the detection limit of the XRD). The diffraction peaks also confirm the stability of the synthesized silver crystals a significant character that promotes visible light photoexcitation. Overall, the sharp and intense peaks indicate the high crystalline characteristics of all prepared samples. The average crystalline sizes of TiO₂ calculated using Scherrer equations was found to be 17.28 nm where no change was observed after the deposition of Ag NPs indicating perfect surface deposition of Ag NPs. Meanwhile the crystallite size of the Ag particles were calculated to be 7.05 nm, 7.04 nm and 7.38 nm for 1.0wt% Ag/TiO₂, 3.0wt% Ag/TiO₂ and 5.0wt% Ag/TiO₂ respectively.

The phase purity of TiO₂ was confirmed with Raman analysis through four distinct peaks at 145 (E_g), 399 (B_{1g}), 519 (A_{1g} + B_{1g}) and 639 cm⁻¹ (E_g) and is shown in Figure 4.27 (W. Li & Zeng, 2011).

Figure 4.26: X-ray diffraction patterns of (a) TiO₂ (b) 0.5wt% Ag/TiO₂ (c) 1.0wt% Ag/TiO₂ (d) 3.0wt% Ag/TiO₂ (e) 5.0wt% Ag/TiO₂

Figure 4.27: Raman spectra of (a) TiO₂ (b) 0.5wt% Ag/TiO₂ (c) 1.0wt% Ag/TiO₂ (d) 3.0wt% Ag/TiO₂ (e) 5.0wt% Ag/TiO₂

The obtained surface structures of the composite is depicted in Figure 4.28 (a-c). It is evident that synthesized Ag NPs are uniform and homogenous and spherical. The inset of Figure 4.28 (c) shows the EDX spectrum of the synthesized Ag/TiO₂ confirming elemental composition of the prepared photocatalyst. The particles size and lattice fringe of the synthesized samples were acquitted through HRTEM analysis and is illustrated in Figure 4.28 (d-f). The average particles size deposited Ag NPs was between 4 and 8 nm. A 0.24 nm and 0.35 nm fringe spacing was observed through the fringe analysis and is attributed to the face centered cubic (FCC) Ag (1 1 1) and TiO₂ (1 0 1) respectively (D. Chen et al., 2013; Z. Chen et al., 2014; Jiang, Zhou, Mi, & Wu, 2012).

Figure 4.28: FESEM images of (a-c) 3.0wt% Ag/TiO₂. The inset of (c) is the EDX of 3.0wt% Ag/TiO₂ and (d-f) HRTEM images of 3.0wt% Ag/TiO₂

The adsorption-desorption hysteresis of the synthesized samples were presented in Figure 4.29. The samples metaphorised a stepwise adsorption and desorption hysteresis, well described by type IV isotherms based on IUPAC classification with a good mesoporous nature (Pan & Xu, 2013b). This inference was consistent with BJH desorption pore distribution curve and pore diameters (Inset of Figure 4.29 (a) and (b)). A significant reduction in BET surface area ($46.6 \text{ m}^2/\text{g}$) was reported for 3.0wt% Ag/TiO₂ as compare to ($52.2 \text{ m}^2/\text{g}$) TiO₂ was due to partial filling of titania pores by Ag NPs.

Figure 4.29: Adsorption-desorption isotherm of (a) TiO_2 (b) 3.0wt% Ag/TiO_2 and the inset is the pore size distribution

The chemical composition and oxidation state for the synthesized samples is displayed in Figure 4.30. With the presence of two peaks (Figure 4.30 (a)) at the binding energies of 458.06 and 463.65 eV which corresponded to Ti 2p_{3/2} and Ti 2p_{1/2} spin-orbital splitting photoelectrons for anatase TiO₂ respectively (Di Li, Haneda, Labhsetwar, Hishita, & Ohashi, 2005; H. Liu, Dong, Li, Su, & Zhu, 2013). This is attributed to the strong presence of Ti⁴⁺ oxidation state in the synthesized sample (Aziz, Cheng, et al., 2012). The strong existence of Ag NPs can be distinguished through peaks centered at binding energy 367.03 and 373.07 eV corresponding to Ag 3d_{5/2} and Ag 3d_{3/2} respectively with spin energy separation of 6.04 eV (D. Chen et al., 2013; S. F. Chen et al., 2010; Guin, Manorama, Latha, & Singh, 2007; Pan & Xu, 2013a; Zhao, Kuai, & Geng, 2012). Thereby, prove the predominance existence of the Ag NPs in the metallic form as like Pd NPs (F. Xiao, 2012a).

Figure 4.30: Core level XPS spectra of (a) Ti 2p (b) Ag 3d of 3.0wt% Ag/TiO₂

The diffuse reflectance spectra (DRS) were used to determine the optical property of the synthesized sample and illustrated in Figure 4.31. The absorbance spectrum of TiO₂ was well discussed in the descending sections. The spectrum exhibited a strong and wide absorption peak at 570 nm after the deposition on Ag NPs. This significant change is strongly acknowledged to localized surface plasmon resonance (LSPRs) triggered by Ag NPs (Link & El-Sayed, 1999; Ramchiary & Samdarshi, 2014; Roy, Bandyopadhyaya, & Pal, 2004; Zhao et al., 2012; Zheng et al., 2011). The presence of Ag NPs on the titania surface had drastically created disturbance on dielectric constant of the surrounding matrix and contributed for visible light absorption (Ung, Liz-Marzán, & Mulvaney, 1998). It is also noteworthy that the visible light absorption peaks of the various Ag doping are unchanged, except the intensities due to the different in catalyst loading.

Figure 4.31: UV-visible absorption spectra of (a) TiO₂ (b) 0.5wt% Ag/TiO₂ (c) 1.0wt% Ag/TiO₂ (d) 5.0wt% Ag/TiO₂ (e) 3.0wt% Ag/TiO₂

Figure 4.32 shows the studied PL spectrum in order to evaluate the trapping, separation and migration of the photogenerated charge carriers of the synthesized samples. From the results it is well proven that deposition of Ag NPs onto the surface of TiO₂ contributed for reduction of electron and hole recombination's. Thus lay bridge for the excess electrons to be transferred from the Ag valence band (VB) to conduction band (CB) of TiO₂ under photoexcitation. The Ag also well contributes for the prolonged lifetime for the charge carriers. However, with the further increase of Ag loading from 3.0 to 5.0wt%, also increased the PL intensity which is due to redundant of Ag NPs that act as a recombination sites for electrons and holes (Z. Liu et al., 2011).

Figure 4.32: Photoluminescence spectra of (a) TiO₂ (b) 0.5wt% Ag/TiO₂ (c) 1.0wt% Ag/TiO₂ (d) 5.0wt% Ag/TiO₂ (e) 3.0wt% Ag/TiO₂

The synthesized Ag deposited photocatalysts with different loading were evaluated for photocatalysis by degrading two different genera of pollutants under the artificial visible light irradiation. The study demonstrated a superior photocatalytic performance for both the pollutants. Figure 4.33 (a) depicted the photocatalytic degradation efficiency of AMX. 3.0wt% Ag/TiO₂ achieved the highest efficiency of 63.48% followed by 61.06%, 57.66%, 28.73% and 27.88% for 5.0wt%, 1.0wt%, 0.5wt% Ag/TiO₂ and TiO₂ respectively. Similar observation (Figure 4.33 (b)) was also inferred for 2, 4-DCP where the highest efficiency was obtained for 3.0wt% Ag/TiO₂ (60.23%) as compare to 5.0wt% Ag/TiO₂ (59.17%), 1.0wt% Ag/TiO₂ (55.99%), 0.5wt% Ag/TiO₂ (15.21%) and TiO₂ (14.14%). Under the absence of photocatalyst, almost negligible degradation was observed for both the EDCs clarifying that they are not of

photosensitising category. The deposition of Ag NPs, well acknowledged the visible light driven photoexcitation and this notable improvement was attributed to the unique characteristics of noble metals, i.e., localized surface plasmon resonance (LSPR) which enables Ag NPs to strongly absorb light in the visible spectrum. The charge density is redistributed and thus establishes a strong coulombic restoring force further resulted in oscillation of charge density like a harmonic oscillator in phase with the incident light (Kochuveedu et al., 2013; Lang et al., 2014; Qu & Duan, 2013; Zhou et al., 2012). Thus occurred oscillation distressed the dielectric constant of the surrounding matrix (Ung et al., 1998). The Ag NPs leads to the formation of Schottky barrier at the interface of Ag-TiO₂ and promotes the transport of excited electrons from Ag interface to the TiO₂ due to the strong electric field (Bumajdad & Madkour, 2014; Xiang et al., 2010). This electric field forced both the photogenerated electrons and holes on Ag NPs to isolate each other. These entire phenomenon's are apparently contributed for the reduction of recombination rate of electron-hole pairs and prolong the lifetime of the charges carriers (Qi, Yu, Liu, & Wong, 2014; Xiang et al., 2010; X. Zhang et al., 2013).

Figure 4.33: Photocatalytic degradation of (a) AMX (b) 2, 4-DCP under artificial visible light irradiation

Figure 4.34 illustrates the degradation mechanism promoted through electron transfer in the photocatalytic activity. When Ag/TiO₂ is irradiated with visible light the electrons lying below the Fermi level (E_f) of Ag NPs gets excited to the surface plasmon states, leaving positive charges (h^+) below the E_f . Thus, with the contact of Ag NPs on the surface of TiO₂, the energetic electrons from Ag excites to the CB of TiO₂. As the CB of TiO₂ is an electron acceptor, it readily accepts the electrons and forms superoxide anion radicals ($\cdot O_2^-$) and followed by the protonation and yields $\cdot HO_2$ radicals. This $\cdot HO_2$ radicals easily combines with the trapped electrons resulting H₂O₂ and finally forming a photodegradation active species $\cdot OH$ radicals. Moreover Schottky barrier was formed at the interface of Ag/TiO₂ because the Fermi level of TiO₂ is higher than that of Ag which will hinder the transfer of electron from the Ag to TiO₂. However, it is evident that

electrons are capable to transfer from Ag to TiO₂ due to its strong electron oscillation collectively through SPR excitation. These lead to interband excitation giving sufficient energy to the electrons to overcome the Schottky barrier at the interface of Ag/TiO₂ (Kochuveedu et al., 2013; Wen, Ding, & Shan, 2011; M. Xiao et al., 2013). Thus it triggers the energetic electron to be transferred to the CB of TiO₂ and lead to the enriched formation of [•]OH radicals thus enhancing the photocatalytic oxidation.

Figure 4.34: Schematic diagram of photocatalysis mechanism Ag/TiO₂ photocatalyst under artificial visible light irradiation

As like Pd the importance of optimal loading was also studied for Ag and correlated with photocatalytic performance. The photocatalyst with low Ag loading (0.5wt% Ag/TiO₂) exhibited a weak performance with only 28.73% for AMX and 15.21% for 2, 4-DCP. This poor performance was due to the low absorption capacity of the photocatalyst in the visible region (D. Chen et al., 2013). On the other hand, high Ag loading (5.0wt% Ag/TiO₂) also resulted in poor performance due to the overlapping of the plasmonic field region. Besides that, it also promoted shielding effect of Ag layer and marginally declined the photocatalytic performance as observed in Pd composite (W. Wang et al., 2012). Therefore the optimal Ag loading content found to be 3.0wt% that delivered the best photocatalytic efficiencies in accordance to LSPR effect and Schottky interface. The photocatalytic degradation of both the AMX and 2, 4-DCP followed the pseudo first-order reaction kinetics as shown in Figure 4.35 and the rate constants (k_1) are summarized in Table 4.4.

Figure 4.35: The kinetics of (a) AMX and (b) 2, 4-DCP degradation

Table 4.4: The obtained kinetic constants along with the coefficient of regression for AMX and 2, 4-DCP degradation

First Order Kinetics				
Sample	AMX		2, 4-DCP	
	K	R ²	k	R ²
TiO ₂	0.0009	0.978	0.0005	0.975
0.5wt% Ag/TiO ₂	0.0011	0.988	0.0006	0.978
1.0wt% Ag/TiO ₂	0.0031	0.959	0.0025	0.973
3.0wt% Ag/TiO ₂	0.0039	0.954	0.0029	0.982
5.0wt% Ag/TiO ₂	0.0035	0.951	0.0027	0.979

The degree of mineralization presented in Figure 4.36 also well supported the above findings and also well correlated with the liquid chromatography quantification. An efficiency of 51.5% and 43.6% were achieved for mineralization of AMX and 2, 4-DCP by 3.0wt% Ag/TiO₂ respectively. Thus it also proved that the deposition of Ag onto TiO₂ photocatalysts also exhibited a strong oxidation as like palladium under visible light with varied contribution.

Figure 4.36: TOC analysis of AMX and 2, 4-DCP

Though both the noble metals proved their candidature as a good visible light enhancer along with the suppressing the recombination rate of TiO₂ but the achievement could not be denoted as the superior. Hence the modification of the titania was continued by further incorporating with conducting carbon source. The Ag was chosen as one of the composite from the above study owing to the unique size sensitive nature of palladium. The chosen impurities will notably appraise the visible light enhancement and charge separation through its traditional inherent nature.

4.4 Reduced Graphene Oxide (RGO) Wrapped Ag/TiO₂ Photocatalyst

Figure 4.37 details the XRD spectra of the synergized composite RGO-Ag/TiO₂ along with RGO-TiO₂ composite and the synthesized pristine GO, TiO₂ employed in the composite. The analysis and discussion on TiO₂ was discussed well in the descending section. The synergized composite showed diffraction peaks at $2\theta = 38.1^\circ$, 44.3° , 64.4° , 77.4° which corresponded to crystal phase (1 1 1), (2 0 0), (2 2 0) and (3 1 1) respectively (JCPDS no. 04-0783). The intense diffraction peaks also confirm the stability of the synthesized silver NPs through sustainable photo deposition. A diffraction peak at $2\theta = 10.6^\circ$ (0 0 2) was observed for GO sample signifying almost complete oxidation of natural graphite into GO through d-spacing expansion from 3.37 to 8.6 Å. This prove the incorporation of oxygen containing group on to the GO sheets (J. Zhang, Xiong, & Zhao, 2011).

Once the reduction of GO is complete no diffraction peak was observed in the composite samples that consists RGO. This was owing to small amount of carbon species in the composites and is beyond the detection limit (W.-S. Wang, Wang, Qu, Lu, & Xu, 2012; Y. Wang et al., 2013a; C. Zeng et al., 2013). Overall, the sharp peaks seen in all sample indicating the high crystalline characteristics. The crystalline grain size of TiO₂ was independent of composites (Ag and RGO).

Figure 4.37: XRD patterns of (a) GO, (b) TiO₂, (c) RGO-TiO₂, (d) RGO-Ag/TiO₂

The Raman spectrum shown in Figure 4.38 illustrates the distinct peaks for anatase was observed in this case also. The inset of Figure 4.38 shows the Raman spectrum of GO with two intense peaks at 1351 cm⁻¹ (D-band) and 1605 cm⁻¹ (G-band). The D-band resembles the disorder band related with structural imperfections created in the reduced graphene oxide during the reduction of GO by hydrothermal process. Meanwhile, the G-band corresponds to the first order scattering of E_{2g} phonon of sp² C atoms of graphene (Shah et al., 2013). Therefore, the intensity ratio (I_D/I_G) for GO was 0.78 signifying the presence of large amount of sp³ domain in the GO sample. The D- and G-band of RGO-TiO₂ and RGO-Ag/TiO₂ were approximately in the same position with GO. However, the I_D/I_G ratio of RGO-TiO₂ (0.95) and RGO-Ag/TiO₂ (0.97) increased from 0.78 for GO, proved the reduction of GO achieved through hydrothermal process. The adopted process was successful whereby some of the oxygenated groups leading to re-establishment of conjugated graphene network are eliminated (Yang, Tian, Wang, &

Fu, 2011). Through the Raman analysis, it could also verify the charge transfer between GO and the hybridized components. This was shown in the G-band of GO having a slight shift of $\sim 9 \text{ cm}^{-1}$ to a lower frequency at 1596 (RGO-Ag/TiO₂) from 1605 cm^{-1} (GO) confirms the charge transfer between the two hybrid composites where RGO-Ag/TiO₂ acts as an electron donor while GO as an electron acceptor (M. Zhu, Chen, & Liu, 2011).

Figure 4.38: Raman spectra of (a) TiO₂, (b) RGO-TiO₂, (c) RGO-Ag/TiO₂ and inset is the (d) GO

The FESEM images (Figure 4.39 (a) and (b)) illustrated the successful wrapping of RGO and Ag NPs with TiO₂. The image (Figure 4.39 (a)) clarifies the uniform distribution of Ag/TiO₂ onto the RGO sheets and (Figure 4.39 (b)) Ag NPs onto the surface of TiO₂ through efficient sustainable photodeposition method. The HRTEM images shows the average particle size of Ag NPs is between 7 and 9 nm (Figure 4.39 (c)) with a lattice fringes spacing of 0.24 nm and 0.35 nm (Figure 4.39 (d)). The observed

fringes signifies the presence of Ag NPs (1 1 1) and TiO_2 (1 0 1) respectively (D. Chen et al., 2013; Z. Chen et al., 2014).

Figure 4.39: FESEM images of the (a-b) RGO-Ag/TiO₂ and (c-d) HRTEM images of RGO-Ag/TiO₂

The adsorption-desorption hysteresis loop of the synthesized photocatalysts are illustrated in Figure 4.40 (a-c). All the obtained hysteresis well correlated to the type IV isotherms with mesoporous structure. The BET surface area for all the samples was found to be 52.24 m²/g for TiO₂, 61.47 m²/g for RGO-TiO₂ and 73.68 m²/g for RGO-Ag/TiO₂ respectively. The surge in surface area of the synergized composite was contributed by the RGO. It also further shows a well distribution of RGO sheets onto the surface of TiO₂ (Ryu et al., 2015).

Figure 4.40: Adsorption hysteresis of (a) TiO₂, (b) RGO-TiO₂ and (c) RGO-Ag/TiO₂ and the inset is the pore size distribution

The FTIR spectra of all prepared samples are illustrated in Figure 4.41. The GO displayed several robust absorption peaks corresponding to various oxygen functional groups. The absorption peaks included the wide broad peak at 3400 cm^{-1} which correspond to O-H stretching. The carboxylates C=O stretching occurred at 1730 cm^{-1} while the hydroxyl groups of molecular water bending and C=C stretching indicated the absorption at 1620 cm^{-1} . The carboxyl group, phenolic C-O-H and C-O stretching vibrations in the epoxy was detected at 1375 , 1220 and 1045 cm^{-1} respectively (Tan et al., 2013). A distinct and drastic decrease in intensity of absorption peaks was observed at C=O (1750 cm^{-1}), C=C (1620 cm^{-1}), C-O-H (1220 cm^{-1}) and C-O (1045 cm^{-1}) that corresponds to oxygen functional groups contributed by the reduction of GO. Meanwhile, TiO₂ NPs shown wide peaks at 3350 and 1630 cm^{-1} which is ascribed to the O-H group of water, whereas the wide and broad peaks at $500\text{-}900\text{ cm}^{-1}$ is to the stretching vibration of Ti-O-Ti and Ti-O-C bonds. (Yueli Liu et al., 2014).

Figure 4.41: Functional group spectra of (a) GO, (b) TiO₂, (c) RGO-TiO₂ and (d) RGO-Ag/TiO₂

The XPS spectra of the prepared samples were presented in Figure 4.42 (a-d). Figure 4.42 (a) shows the C 1s XPS spectrum of GO with generally can be devolved into four peaks at 284.8, 286.6, 287.8 and 289.0 eV and this binding energies corresponds to different functional group of C-C and C-O in hydroxyl or epoxy forms, C=O and COOH respectively (D. Wang, Li, Chen, & Tao, 2012; H. Zhang et al., 2011). After the hydrothermal treatment at 180°C for 6 h, significant decrease of contents C-O and C=O peaks of C 1s observed in the synergized composite sample (RGO-Ag/TiO₂) indicating the substantial removal of oxygen containing groups during the treatment (Figure 4.42 (b)). This significant decrease in the oxygen concentrations shows a remarkable effectiveness in reduction of GO. Figure 4.42 (c) illustrated the Ti core level XPS spectrum where two peaks centered at 459.8 eV (Ti 2p_{3/2}) and 465.5 eV (Ti 2p_{1/2}) as seen in our previous studies. The presence of Ag NPs were represented in Figure 4.42 (d) with two peaks centered at 368.6 and 374.6 eV for Ag 3d_{5/2} and Ag 3d_{3/2} respectively with 6 eV splitting between two peaks.

Figure 4.42: Core level XPS spectrum of (a) C 1s of GO, (b) C 1s of RGO-Ag/TiO₂, (c) Ti 2p and (d) Ag 3d

In scrutinize the absorption of the synthesized materials, UV-visible absorption spectroscopy analysis was executed and shown in Figure 4.43. A considerable red shift towards visible light region is clearly observed for RGO-TiO₂ and RGO-Ag/TiO₂ indicating narrow band gap energy with the introduction of RGO. This significant shift ascertain the incorporation of RGO in the composite through Ti-O-C bond (Shah et al., 2013; Yuhao Yang et al., 2014). Further enhancement in the visible light region at ~ 460 nm was noticed after the incorporation of Ag NPs into the composite (RGO-Ag/TiO₂) (Shah et al., 2013). The existence of Ag NPs on the surface of TiO₂ significantly oscillated the dielectric constant surrounding the matrix leading to the visible light absorption. The Figure 4.44 reveals the calculated band gap energy for the prepared photocatalysts by using Kulbeka-Munk equation. It was found that after the incorporation of RGO the band

gap energy of TiO_2 was narrowed to 2.9 eV. The reduction in band gap was attributed to the formation of Ti-O-C bond, where the free electrons on the surface of TiO_2 are bonded with unpaired π -electrons and leading to a shift upwards the valence band edge (Umrao et al., 2014). The observed phenomenon enhanced the RGO-Ag/ TiO_2 with a notable visible light performance.

The photoluminescence spectra for the prepared samples were portrayed in Figure 4.45. It is well proven from the analysis that the composite RGO and Ag NPs had drastically reduced the recombination rate of electron-hole pairs. This is attributed to the trapping of the photo-excited electrons by RGO (Shah et al., 2013). A more active separations of electron-hole pairs was observed after the incorporation of Ag NPs. This resulted from the effective electrons transfer from TiO_2 - Ag NPs - RGO. Therefore, it is clear that RGO-Ag/ TiO_2 composite exhibited a better photocatalytic performance.

Figure 4.43: UV-vis absorption spectra (a) TiO_2 , (b) RGO- TiO_2 and (c) RGO-Ag/ TiO_2

Figure 4.44: Calculated band gap energy of (a) TiO_2 , (b) RGO-TiO_2 and (c) RGO-Ag/TiO_2

Figure 4.45: Photoluminescence spectra of (a) TiO_2 , (b) RGO-TiO_2 and (c) RGO-Ag/TiO_2

Figure 4.46 (a-c) clearly shows the visible light photocatalytic degradation efficiency of the prepared photocatalysts. It was clearly observed that the degradation efficiency followed an order of $\text{RGO-Ag/TiO}_2 > \text{RGO-TiO}_2 > \text{TiO}_2$. It is evident that BPA is very stable and possesses poor photosensitizing nature where almost nil degradation was observed in the presence of visible light alone. An improved comprehensive degradation was achieved by RGO-TiO_2 for BPA compounds within 6 h. The attained improvement on visibility was attributed to the enhancement of the significant red shift through Ti-O-C bond. The bond formation was appraised by the oxygen sites in the TiO_2 lattice and was substituted by carbon atoms (Dong, Wang, & Wu, 2009). Therefore, when visible light illumination is enabled, the photoexcitation took place in the O-2p orbital to Ti-3d orbital and leaves behind holes at the O-2p state with a very high redox potential (Umrao et al., 2014). This high redox potential catalyse the reaction between holes and H_2O leading to the formation of active $\cdot\text{OH}$ radicals. The high redox potential also allows ease transfer of photogenerated electrons from TiO_2 to RGO due to work functions of RGO (4.4 eV) that underlay below the conduction band of TiO_2 (4.2 eV) (Y. Wang et al., 2013). These electrons then react with adsorbed O_2 to form superoxide anion radical ($\cdot\text{O}_2^-$). Thus, it prolongs the lifetime of electron and hole pairs (P. Wang et al., 2013; Y. Wang et al., 2013).

A good photodegradation efficiency of 61.9% was observed for the RGO-Ag/TiO_2 than that of RGO-TiO_2 (39.5%) and TiO_2 (22.2%). It is well evident that this greater efficiency was equally attributed to the inclusion of Ag NPs into the composite. The Ag NPs with a characteristic of negative work function (4.26 eV) stimulated the ability to capture the photogenerated electrons of TiO_2 . When these NPs get intimated with RGO, it further transfers the electrons to the surface of RGO. Hence it further suppresses the charge recombination and thereby increasing the overall photocatalysis efficiency. Moreover the LSPR phenomenon triggered by the noble metal also well

contributed for the visible light enhancement. The presence of visible light excited the Ag surface plasmon and this collective electron oscillation generates high concentration of energetic electrons at its surface. The RGO surface then quickly transports those electrons from Ag surface through extended π -conjugation structure. This movement of electron from Ag to RGO surface prolongs the life span of the charge carriers (Bhunia & Jana, 2014). The excess formation of electrons through Ag also reacts with surface absorbed oxygen forming superoxide anion radical (O_2^-). Where else the holes forms active radicals (OH^\bullet) by reacting with H_2O molecule. Thus the immense production of OH^\bullet radicals triggered through respective mechanism contributed for enhanced suppression of electron-holes recombination. The proposed mechanism for the photocatalytic degradation of poor sensitizing compound under visible light irradiation is illustrated in Figure 4.47.

Meanwhile, a similar experiment was also carry out to evaluate the good photosensitizing compounds namely anionic (Reactive Blue 19-RB19) and cationic (Methylene Blue-MB) dye pollutants. From Figure 4.46 (b) and (c) clearly show the similar photodegradation efficiency trend as BPA compounds. However, both RGO-TiO₂ and RGO-Ag/TiO₂ exhibited a high absorption capacity for MB as compared to RB19 and BPA. This phenomena was mainly due to the strong formation of $\pi - \pi$ stacking interaction between the benzene ring of MB and the surface of RGO (T. Wu et al., 2011). The high degradation efficiency observed in both the dyes was mainly due to the presence of RGO and Ag NPs along with the photosensitizing nature. In most cases the RGO act as an electron sink to facilitate photo generated electrons separation and store the separated electrons (Ping Wang, Zhai, Wang, & Dong, 2011). Moreover, RGO can accumulate electrons injected from the photo generated dyes because of the π -conjugated network that increase the photocatalytic degradation efficiency.

VACUUM LEVEL

Figure 4.47: Schematic diagram of photocatalysis mechanism of RGO-Ag/TiO₂ photocatalyst under artificial visible light irradiation

Recycle experiments were carried out to evaluate the stability of the prepared photocatalysts. It clearly shows in Figure 4.48 (a-c) that the RGO-Ag/TiO₂ still sustains a high level of degradation efficiency even after three rounds of recycling. An efficiency of 56.3% was able to accomplish after the third run. Similarly complete removal MB and RB19 was achieved as compared to the first run showing with marginal increases in reaction time.

Figure 4.48: Stability analysis of prepared photocatalysts (a) BPA, (b) MB and (c) RB19

The kinetics of degradation best fitted the pseudo first-order reaction kinetics and the results are illustrated in Figure 4.49 (a-c) and the kinetics parameters are tabulated in Table 4.5. The degree of mineralization are depicted in Figure 4.50 (a) and (b).

Table 4.5: Kinetic parameters obtained on various pollutants degradation

First Order Kinetics						
Sample	MB		RB19		BPA	
	k	R ²	k	R ²	k	R ²
TiO ₂	0.0025	0.9959	0.0008	0.9990	0.0005	0.9949

The synergisation of the Ag and RGO proved their candidature as a good visible light enhancer and also prolonged the life time of the charge carrier of TiO_2 . The photocatalysis with varied pollutant also demonstrated the ability of the synergized composite. However a exploring the potential of a semiconductor carbon compound could of more interest and valued for the visible light enhancement. Hence the study was further extended by choosing one such semiconductor carbon compound, Graphitic Carbon Nitride ($\text{g-C}_3\text{N}_4$).

4.5 Graphitic Carbon Nitride Incorporate with Ag/ TiO_2 Photocatalyst

The prepared novel ($\text{g-C}_3\text{N}_4$)-Ag/ TiO_2 composite was analyzed for the phase composition and was presented in Figure 4.51. The presence of two peaks at $2\theta = 13.1^\circ$ and 27.4° are attributed to the interlayer stacking of $\text{g-C}_3\text{N}_4$ that indexed as (0 0 1) and (0 0 2) respectively. The presences of Ag NPs are detected with the occurrence and are well supported with JCPDS no 04-0783. It is noted that no typical diffraction peaks of $\text{g-C}_3\text{N}_4$ appeared for composites due to the low amount of loading on the surface of the nanocomposite (Y. Chen et al., 2014). Figure 4.52 displayed the Raman spectrum that well correlated with XRD analysis proven the presence of anatase phase of the prepared TiO_2 and the respective peaks are denoted in the figure.

Figure 4.51: XRD pattern of (a) $\text{g-C}_3\text{N}_4$, (b) TiO_2 , (c) $(\text{g-C}_3\text{N}_4)\text{-TiO}_2$, (d) Ag/TiO_2 and (e) $(\text{g-C}_3\text{N}_4)\text{-Ag/TiO}_2$

Figure 4.52: Raman spectra of (a) TiO_2 , (b) $(\text{g-C}_3\text{N}_4)\text{-TiO}_2$, (c) Ag/TiO_2 and (d) $(\text{g-C}_3\text{N}_4)\text{-Ag/TiO}_2$

The morphology of the (g-C₃N₄)-Ag/TiO₂ was illustrated in Figure 4.53 (a-f). It is clearly seen that the g-C₃N₄ is well distributed onto the surface of Ag/TiO₂. The high resolution image of Figure 4.53 (d) clarified more uniform photodeposition of Ag NPs onto the surface of TiO₂ similar to our earlier findings. The average particles size of Ag NPs captured through HRTEM images are in range of 4 – 6 nm. Figure 4.53 (f) depicts the lattice fringes that denotes the presence of Ag NPs (0.24 nm) and TiO₂ (0.35 nm) in the prepared photocatalysts.

Figure 4.53: (a) FESEM image, (b-f) HRTEM images of (g-C₃N₄)-Ag/TiO₂

The functional group analyses of the prepared nanocomposites are illustrated in Figure 4.54. An intense band recorded at 1641, 1570, and 1410 cm^{-1} was assigned to the stretching vibration modes of aromatic C-N and proved the successful synthesis of g-C₃N₄ (J. Liu et al., 2011). The sharp band at 807 cm^{-1} is attributed to the out-of plane bending vibration characteristic of triazine units (J. Liu et al., 2011; Y. Chen et al., 2014). Meanwhile, the bands at 1320 and 1240 cm^{-1} are resembled to the stretching vibration of connected unit of C-N (-C)-C or C-NH-C. This is also well correlated with the stretching vibration of hydrogen bonding interaction with a broad band in-between 3100-3300 cm^{-1} (J. Liu et al., 2011). Where else a broad band at 3350 cm^{-1} represents the O-H group of water molecule. In addition, the presence of wide absorption band at 500-700 cm^{-1} is ascribed to the Ti-O-Ti bonding (Umrao et al., 2014; Yueli Liu et al., 2014). The Ag/TiO₂ also showed a similar absorption bands as that of TiO₂. The obtained spectrum

successfully shown the key characteristic bands for g-C₃N₄ and TiO₂ appeared in the nanocomposites indicating the accomplishment of the synthesis route.

Figure 4.54: FTIR spectra of (a) g-C₃N₄, (b) (g-C₃N₄)-TiO₂, (c) (g-C₃N₄)-Ag/TiO₂, (d) TiO₂ and (e) Ag/TiO₂

Figure 4.55 explicates the X-ray photoelectron spectra that shows the surface chemical composition of each elements for the prepared (g-C₃N₄)-Ag/TiO₂ photocatalyst. The spectrum displayed all the basic elements of the nanocomposite. The C 1s spectrum displayed two distinct peaks located at 284.9 and 288.1 eV. These peaks are attributed to C-C coordination including the adventitious hydrocarbon and the sp² hybridized carbon atom existent from g-C₃N₄ nanosheets. While the peak at 288.1 eV is ascribed to N-C=N coordination. The N 1s spectrum displayed three peaks that ascribed to C=N-C at 398.6 eV, N-(C)₃ at 399.8 eV and C-N-H at 401.1 eV whereas the O 1s spectrum exhibited two peaks at 530.1 and 531.8 eV corresponds to Ti-O bond and O-H bond respectively. The

occurrence of O-H bond was due to the presence of water molecule on the surface of (g-C₃N₄)-Ag/TiO₂. Furthermore, the Ti 2p spectrum also showed two distinct peaks at 458.9 eV (Ti 2p_{3/2}) and 464.6 eV (Ti 2p_{1/2}). As usual two typical peaks for Ag 3d was seen at 368.6 eV and 374.6 eV are ascribed to Ag 3d_{3/2} and Ag 3d_{5/2}.

Figure 4.55: X-ray photoelectron spectra of (a) C 1s, (b) N 1s, (c) O 1s, (d) Ti 2p and (e) Ag 3d

The optical properties of the prepared photocatalysts are analysed using UV-vis diffuse reflectance spectroscopy. Figure 4.56 displayed the absorbance spectra of the (g-C₃N₄)-Ag/TiO₂, Ag/TiO₂ and (g-C₃N₄)-TiO₂ nanocomposite, together with those pure TiO₂ and g-C₃N₄. As proven in our previous studies, the absorption edge of pure TiO₂ only occurs at wavelength shorter than 390 nm. However, pure graphitic carbon nitride rises the absorption intensity edge to about 460 nm. Therefore by incorporating g-C₃N₄ onto the surface of TiO₂ drastically increased the absorption intensity in-between 390-460 nm and shifted the absorption edge to 460 nm.

Thus the g-C₃N₄ greatly improved the absorption ability of TiO₂ in the visible light region. In addition the incorporation of noble metal (Ag) onto the surface of TiO₂ also enhanced the absorption ability in the visible spectrum. The absorption curve of ternary composite (g-C₃N₄)-Ag/TiO₂ displayed a distinct shift towards the visible light spectrum as compared to the rest. The band gap energies of the prepared photocatalysts were estimated through Kubelka-Munk equation and the obtained band gap calculation is depicted in Figure 4.57 (a-e). The TiO₂ resulted with well-known band gap energy 3.2 eV where else the g-C₃N₄ with 2.7 eV. The chosen composite very well contributed for tuning of band gap and was narrowed to 3.0, 3.1 and 2.5 eV for (g-C₃N₄)-TiO₂, Ag/TiO₂ and (g-C₃N₄)-Ag/TiO₂ respectively.

Figure 4.56: UV-vis absorption spectra of (a) TiO₂, (b) (g-C₃N₄)-TiO₂, (c) g-C₃N₄, (d) Ag/TiO₂ and (e) (g-C₃N₄)-Ag/TiO₂

Figure 4.57: Calculated band gap energy of (a) TiO_2 , (b) $\text{g-C}_3\text{N}_4$, (c) $(\text{g-C}_3\text{N}_4)\text{-TiO}_2$, (d) Ag/TiO_2 and (e) $(\text{g-C}_3\text{N}_4)\text{-Ag/TiO}_2$

Figure 4.58, portraits the life time of the charge carries. The g-C₃N₄ demonstrated a rapid recombination of charge carriers as compared to the rest by showing the highest light emission after the absorption of illuminated photons. However the phenomenon drastically reduced after incorporating g-C₃N₄ with TiO₂.The g-C₃N₄ prolonged the lifespan of the electron by allowing the electrons to be transferred from g-C₃N₄ to the conduction band of TiO₂. In comparison, the photoluminescence intensities of Ag/TiO₂ and (g-C₃N₄)-Ag/TiO₂ are lower than that of the pure TiO₂ indicates the good separation of charge carriers in Ag/TiO₂ and (g-C₃N₄)-Ag/TiO₂. The Photoluminescence results clearly demonstrated the formation of heterostructure between (g-C₃N₄) and Ag/TiO₂. The heterojunction allows the electron transferring from g-C₃N₄ to Ag NPs and then finally being transported to the conduction band of TiO₂ for potential redox reactions. Thus formed heterostructure blocked the recombination of electrons and holes and prolonged the lifetime.

Figure 4.58: Photoluminescence spectra of (a) g-C₃N₄, (b) (g-C₃N₄)-TiO₂, (c) TiO₂, (d) Ag/TiO₂ and (e) (g-C₃N₄)-Ag/TiO₂

The visible light photocatalysis ability was evaluated by adopting AMX and well known endocrine disrupting compound. The photocatalytic degradation profile of the AMX with aid of prepared photocatalysts is illustrated in Figure 4.59. The degradation followed an order of (g-C₃N₄)-Ag/TiO₂ (73.4%) > Ag/TiO₂ (56.2%) > (g-C₃N₄)-TiO₂ (38.9%) > g-C₃N₄ (35.1%) > TiO₂ (22.7%).

Figure 4.59: Artificial visible light photocatalysis performance of prepared photocatalysts

As expected a poor photodegradation efficiency was exhibited by TiO₂ owing to non-visible light sensitive. While wrapping of g-C₃N₄ with TiO₂ showed an increase in photodegradation efficiency 1.7 times than TiO₂. This was attributed to the characteristics of g-C₃N₄ which stimulated the visible light absorption. Further a remarkable increase of photocatalytic degradation by 3.2 times than TiO₂ was successfully achieved for (g-C₃N₄)-Ag/TiO₂. With further additional of Ag NPs to the (g-C₃N₄)-TiO₂ triggered the

visible light absorption characteristics through an intrinsic surface plasmon resonance and also extended the separation time of charge carriers.

From the obtained materials chemistry and photodegradation profile the mechanism behind the prepared ternary photocatalyst is metaphorized in Figure 4.60. The edge potential of CB and VB of a semiconductor can be estimated based on the following equations:

$$E_{VB} = \chi - E^e + 0.5 E_g \quad (4.5)$$

$$E_{CB} = E_{VB} - E_g \quad (4.6)$$

where E_{VB} and E_{CB} is the valence band and conduction band edge potential respectively, χ is the electronegativity of the semiconductor; E^e is the energy of free electrons on the hydrogen scale (about 4.5 eV vs NHE) and E_g is the band gap energy of the semiconductor. The electronegativity of g-C₃N₄ and TiO₂ are 4.64 and 5.81 eV respectively (Y. Chen et al., 2014).

Based on the calculation, the CB and VB edge potential of g-C₃N₄ were at -1.21 and 1.49 eV respectively. Meanwhile for TiO₂, the CB was found to be -0.29 eV and the VB was 2.91 eV. During the visible light illumination, g-C₃N₄ dominates TiO₂ owing to its tendency to absorb visible light and produces electrons and holes. The prevailing negative edge potential of g-C₃N₄ (-1.21 eV) allows the photogenerated electrons to be transferred to the lower negative edge potential of CB of TiO₂ (-0.29 eV). It is well-known that the redox potential of O₂/[•]O₂⁻ (-0.33 eV) is more negative than the CB of TiO₂ (-0.29 eV) and hence the transferred electrons in the CB of TiO₂ are not favourable to reduce the O₂. Instead, these electrons can reduce O₂ to H₂O₂ (O₂/H₂O₂ is 0.695 eV) and the formed H₂O₂ would further transformed into [•]OH by capturing an electron. Meanwhile, the holes in the VB of g-C₃N₄ can directly oxidise the AMX, but not the OH⁻ to generate

$\cdot\text{OH}$ radicals due to lower positive potential of VB of g- C_3N_4 (1.49 eV) against standard redox potential of $\cdot\text{OH}/\text{OH}^-$ (1.99 eV). In the ternary composite the presence of Ag NPs onto the surface of TiO_2 played a key role as an electron-conduction bridge. This enabled a notable electron-holes separation in g- C_3N_4 and also enhanced the electron transfer towards TiO_2 through Schottky barrier between Ag and TiO_2 . Therefore the excited electrons from g- C_3N_4 directly migrate to Ag/ TiO_2 . Thus it retarded the recombination of electron and holes pairs and promoted more promising photodegradation efficiency. The formation of Schottky barrier between Ag and TiO_2 occurs due to the higher Fermi level (E_f) of TiO_2 than Ag. The formation hinders the transfer of electrons from Ag to TiO_2 . However, the barrier was shattered and the transfer was possible due to strong electron oscillating on the LSPR excitation and leads to the interband excitation. Thus, it triggers the energetic electron to be transfer to the TiO_2 conduction band. Moreover the LSPR effect of Ag NPs also significantly contributed for the visible light absorption of the ternary. The presence of visible light excites the electrons below the Fermi level of Ag NPs to the surface plasmon states. Thus, this excitation contributed to the high generation of energetic electrons. These electrons migrates to TiO_2 which then reduce the O_2 to H_2O_2 and further transformed into $\cdot\text{OH}$ radicals. This aggressive formation of electrons contributed to the better photocatalytic performance.

Figure 4.60: Schematic diagram of photocatalytic mechanism of (g-C₃N₄)-Ag/TiO₂

The kinetics of the photocatalytic activities well fitted with pseudo first-order reaction kinetics and the results are depicted in Figure 4.61 and Table 4.6. The recyclability experiments were performed and depicted in Figure 4.62. The photocatalysis of (g-C₃N₄)-Ag/TiO₂ for AMX declined marginally after three cycles. However the photocatalytic efficiency was not much affected.

Figure 4.61: The kinetics fitting for AMX degradation

Table 4.6: Obtained kinetic parameters for prepared photocatalysts

First Order Kinetics					
	TiO ₂	g-C ₃ N ₄	(g-C ₃ N ₄)-TiO ₂	Ag/TiO ₂	(g-C ₃ N ₄)-Ag/TiO ₂
R²	0.9958	0.9976	0.9888	0.9946	0.9986
k	0.00078	0.00127	0.00134	0.00180	0.00340

Figure 4.62: Stability analysis of prepared photocatalysts for AMX degradation

Overall entire present thesis showed the contribution of the chosen composites for enhancing the visible light utilization and prolonging the charge carriers of the conventional TiO_2 . Also the prepared composite photocatalysts well proved the candidature for visible light photocatalysis.

CHAPTER 5

CONCLUSIONS AND RECOMMENDATIONS

5.1 Conclusions

The foremost aim of the thesis was to modify and tune the band gap of conventional TiO_2 that is readily activated through photons generated by the visible light. The foresaid objective was successfully achieved by synthesizing binary and ternary composite with the aid of noble metal and carbon conducting materials. The conclusions for the adopted objectives of the present thesis are as follows:

- The template TiO_2 was successfully achieved with controlled particles size. The calcination step encouraged the photocatalytic performance and shown comparatively better activity by destructing 2, 4-DCP illuminated under solar irradiation.
- The fabrications of heterogeneous plasmonic photocatalysts (Pd/TiO_2 & Ag/TiO_2) were successfully synthesised through smart, ease and sustainable approach.
- The maximize usage of natural sunlight well supported for the reduction and anchoring of studied noble metals onto the TiO_2 yielding classification photocatalysts called “Plasmonic photocatalysts” with enhanced visible light utilisation.
- The formations of localized surface plasmon resonance and Schottky barrier evidently triggered the enhancement of harvesting visible light and prolonged

the lifetime of the charge carriers with an excellent photocatalytic performance.

- The exfoliation of RGO also well promoted the visible light utilisation through stable Ti-O-C bond. It also eased the electron mobilisation that significantly enhance the transport of charge carrier and further extend duration of charge carriers.
- The deployment of Graphitic Carbon Nitride (g-C₃N₄) a unique semiconductor organic compound, drastically surged the visible light absorption intensity, narrowed the band gap energy and shifted the absorption edge to higher wavelength than RGO.
- The proposed photocatalysis mechanisms revealed the unique behaviour expressed by the each element for the visible light enhancement and charge carriers suppression.
- The accomplishment of both noble metals and conducting carbon materials in modified conventional titania contributed for a robust visible light photocatalysis and was well demonstrated through adopted pollutants.

5.2 Recommendations

The following recommendations are to be considered or future research works.

- A scale up study followed by a pilot with the help of a proper reactor could demonstrate real time applications and industrial feasibility.
- The influence of the photons on the degradation could be modelled and simulated by understanding the light interaction on the photocatalyst.

- The quantity of hydroxyl radicals ($\cdot\text{OH}$) could be quantitatively analyzed for additional information on the surface reactions that pave a pathway for an efficient modelling.
